SUMMARY

The western margin of the Askrigg Block has been investigated by regional geochemical reconnaissance. This took the form of a drainage basin survey with the collection of stream sediments (306 samples), panned concentrates (149 samples), and waters (278 samples) over an area of $c.450 \text{ km}^2$. In addition, following an observation of a moss-like plant with tolerance to high levels of base metals, a soil survey was carried out on Tow Scar, 3 km to the northwest of Ingleton.

The drainage basin survey reveals no new major mineralisation though minor mineral shows have been located following investigation of some anomalous sites. The soil survey led to the discovery of minor mineralisation, which suggests that similar occurrences might exist adjacent to the Craven Fault system east of Ingleton.

INTRODUCTION

This report covers the western area of the Askrigg Block, namely the upper part of Wensleydale (west of Hawes), Widdale, Dentdale, Kingsdale and the upper reaches of the Ribble Valley (Figure 1). Generally flatlying or slightly tilted coarse sandstone of Millstone Grit age caps the higher land of the area, the highest peaks of which are Ingleborough (723 m) and Whernside (736 m). Soils range from the poorly drained peats to the very thin soils of the limestone pavement areas. The drainage system occupies broad valleys in which variable amounts of glacial and alluvial material has accumulated.

This area was selected for mineral reconnaissance for a number of reasons.

- There are mineralised areas on the Askrigg Block (e.g. Swaledale and Littondale), and a number of mineralised localities and mines are recorded within the area itself (Figure 2).
- (ii) Its margins are bounded on two sides by major fault structures both of which are associated with mineral deposits.
- (iii) Recently published work by Small (1978), and Ineson and Al-Badri (1980, 1981) suggest that the area has some potential for mineralisation.

Small (1978), in a study of mineralisation controls in the North Pennines, postulates that part of this area lies close to the source of mineralising fluids which he believes were responsible for the extensive ore-field in Wharfedale and Swaledale.

The work of Ineson and Al-Badri is summarised in two publications (1980, 1981) which discuss the data obtained from hydrogeochemical and stream sediment reconnaissance surveys. They demonstrate enhanced values for Zn and Cu in waters in the general area of the present investigation. Stream sediment data also indicate anomalous values (greater than mean plus two standard deviations) for Cu, Co and Ni in the same area. However, these authors were not able to confirm the 'zonation' of Small or recognise any pattern similar to that proposed by Dunham and Stubblefield (1944) for the Greenhow area of the Block.

GEOLOGY AND MINERALISATION

Sediments of Carboniferous age up to and including the Namurian underlie most of the area covered by this investigation (Figure 1). They rest with marked unconformity on steeply folded metamorphosed Ingletonian and Lower Palaeozoic sediments up to Silurian age. These 'basement' rocks outcrop in the valleys of the River Greta near Ingleton and the Ribble at Horton-in-Ribblesdale, and in the area adjacent to the Dent Fault NE of Sedburgh.

The base of the Carboniferous sequence is represented by the Orton Group (Dakyns and others, 1891), in which is included the major part of the most massive of the limestones in the sequence, the Great Scar Limestone, and which outcrops extensively in the valley bottoms and along the lower slopes of the fells. The upper part of the Great Scar is succeeded by a sequence of regularly alternating thin limestones, calcareous shales and sandstones which together comprise the Alston Group. The limestones, although relatively thin, are persistent and traceable throughout the area and the more arenaceous units are lenticular and much less persistent laterally. Arenaceous sedimentation becomes much more significant higher in the succesion with the sandstones and grits of the Millstone Grit Series forming the capping to the mesalike fells. Locally, minor unconformities occur at the base of this Series. The Carboniferous succession has a gentle regional dip to the NNE.

Faulting, normally of moderate throw, has been mapped throughout most of the area but there is an increase in frequency in the north. This is related to the main, approximately E-W oriented, faulting (with related mineralisation) of Swaledale some 2 km beyond the northern margin of the area of investigation. Faults mostly trend NW-NNW and have moderate displacement; disturbance in attitude of affected strata is usually minimal. The major faults that have been used to define the boundaries of the area, the Dent and Craven systems, each have considerable measurable throw and in some areas affect the adjacent rock by oversteepening and contorting of the strata.

Apart from the geochemical investigations referred to earlier, the area has not been subject to modern exploration techniques. Some geophysical data are available for the area from the published 1:625 000 scale aeromagnetic map (Institute of Geological Sciences, 1972) and also gravity data from the 1:250 000 scale Bouguer Gravity Anomaly map (Institute of Geological Sciences, 1977).

Recorded mineral locations within the area are relatively few in number. Some are known to be associated with faulting though no common regional trend is discernible. Galena, sphalerite and chalcopyrite (or the derived carbonates) are the commonly recorded minerals, with some fluorite and baryte localities also known. Gangue material is varied, calcite and quartz being the commonest minerals. Table 1 gives details of mines and mineral occurrences in the Dent - Ingleton **area**.

GEOCHEMICAL RECONNAISSANCE

As the area has a well-developed active drainage system, the regional geochemical investigation was undertaken using stream sediment, panned concentrate and water samples. The stream sediments, 306 in total, were obtained using the techniques described by Plant (1971),

t Compiled from one-inch geological map (sheets 40 & 50), Dakyns and others (1890, 1891), and observations made on location.

and the panned concentrates, 149 in all, by the classical gold panning method to produce about 30 g of concentrate. The stream sediments were analysed by \triangle AS techniques for Cu, Pb, Zn, Ba, Mn and Co at the commercial laboratories of Mather Research Ltd, Rothbury (though Mn and Co are not discussed in this report). The panned concentrates were analysed by XRF, at the laboratories of the Institute in London, for Ce, Ba, Sn, Pb, Zn, Cu, Ca, Ni, Fe, Mn, Ti, Sr and Zr. Additionally 278 samples of surface stream waters were analysed for F by specific ion techniques. In this report only the Ba, Pb, Zn, Cu and Sn values for the panned concentrates are used. All the data from the drainage basin reconnaissance are listed in Appendix 1.

A small area underlain by Great Scar limestone adjacent to the North Craven Fault at Tow Scar

[368 475], approximately 3 km to the NW of Ingleton, was selected as an area to be investigated by soil sampling. Interest in this area was stimulated by the report that two plant species (*Minuartia verna (L.) Hiern* and *Thalaspi alpestre*) which are characteristically tolerant to high heavy metal levels and are normally associated with the environment of old mine spoil heaps, had been identified from this locality (Dr W. Sledge, Leeds University, oral communication, June 1978).

Drainage basin reconnaissance

Data interpretation

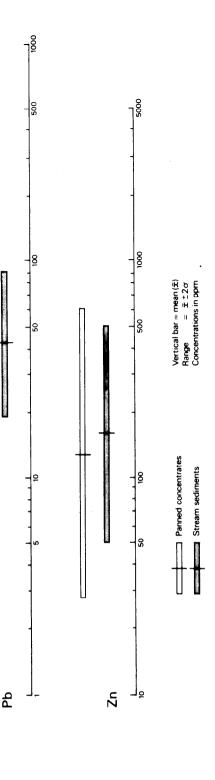

Data from the drainage basin reconnaissance survey have been processed using the G-EXEC relational data base management system on an IBM 360/195 computer at the

ľ

ł

> > 3

8

Rutherford Laboratories, Didcot. The data are presented and interpreted in the following way:-

98 ppm

V

35.5 ppr

Ba

- 1. Locational and analytical data are listed in Appendix 1.
- 2. Element logarithmic means and ranges (range is defined as logarithmic mean <u>+</u> 2 standard deviations) are given in Figure 3 for the stream sediments and panned concentrates.
- 3. Elemental abundances are presented as class interval maps (Figures 4 - 12). Three classes are plotted - the lowest class represents the lowest 84% of the number of samples in the data set, the middle class >84% to <97.5%, and the highest class is the top 2.5%. For the fluoride in water data classes were chosen arbitrarily as the majority of values were uniformly low.
- 4. The Sn data for the panned concentrate samples have been used to indicate artificial contamination - values in excess of 88 ppm Sn (the 92.5% population interval) are regarded as being indicative of contamination. Having identified high Sn samples, contamination has been further investigated by optical examination of the concentrate samples. Results of such examination are indicated in Appendix 2.

Results

From the data derived from the stream sediments and panned concentates, four areas can be defined, each of which contains a number of anomalously high values (see Figure 13).

Area 1, the largest of the areas, lies astride the Dent Fault and may be considered a composite of two

adjacent drainage basins, the most northerly containing streams flowing from the known, and exploited, mineralisation at Cold Keld [3735 4995]. In the north the area is underlain by Carboniferous sediments, but to the southwest, west of the Dent Fault, there are sediments and volcanics of Ordovician and Lower Silurian age.

High barium values identify the mineralisation at Cold Keld and anomalously high levels of Ba, Cu, and Zn are found in Taythes Gill [370 495] flowing over the Lower Palaeozoic into the River Rawthey. Although available published literature does not indicate the presence of any mineralisation from this well-faulted area drained by Taythes Gill, the Dent Fault is represented by a zone of crushing which, where it crosses the Gill, is up to 10 m wide and which contains a considerable amount of baryte as a cementing material. Grains of sphalerite have also been noted and the presence of copper minerals is indicated by blue and green carbonates. Evidence of mineralisation is also seen in the predominantly shale and mudstone succession of the Ordovician Ashgill Series as calcite and quartz veining.

Area 2 which lies to the east of Area 1, includes tributaries flowing to the River Eden and is underlain by rocks of the Carboniferous succession varying from the carbonate/shales of the Alston Group to the grits and sandstones of the overlying Namurian. High copper values are common here, up to twice the calculated mean for the sediments, reflecting the presence of chalcopyrite in a pair of mineralised NE/SW faults. Anomalously high levels of barium are recorded in the panned concentrates with one value in excess of 12 % Ba (Hazel Gill 3777 4998) derived from a mineralised fault that crosses the catchment of this stream.

In Area 3 at Fossdale [386 494] high Pb, Ba and Zn levels are found in the stream sediments and panned concentrates, which are attributed to an exploited mineralised fault zone. In the stream sediments, the values for Pb, Ba and Zn are 10, 8 and 4 times the mean respectively. Values in the panned concentrates are high: barium up to 10.8 % and lead up to 1.9 %. Zinc, with values over 900 ppm, is seven times higher than the mean.

A further group of samples with anomalous values is located in streams draining from Barbon High Fell [367 482] (Area 4). Here the bedrock is composed of Carboniferous sediments, chiefly carbonates, faulted against the Upper Silurian to the west. Values for Cu in the stream sediments are generally only at the mean while lead attains levels about twice mean and zinc up to four times. Barium is also generally higher than background with a maximum of 540 ppm Ba. A maximum value of 0.7 % Ba is recorded from one of the sites in a panned concentrate [3662 4837], together with 488 ppm Pb and 1896 ppm Zn. There are no reported occurrences of mineralised veins and a more detailed examination of the outcrops revealed only minor occurrences of calcite, occupying joints and occasional bedding planes. Pyrite, both as discrete cubes and forming larger irregular patches, was observed in some of the limestones. A thin coal, stratigraphically close to the top of the Alston Group, has been worked in a number of places within this catchment.

The enhanced values for Ba, Pb and Zn in Area 4 may be accounted for by the distribution of very minor amounts of baryte, galena and sphalerite associated with the minor veining and joint fillings, or they may be due to the lithological change from mainly carbonate rocks in the Carboniferous sequence to the shales and mudstones of the Silurian which carry higher values of these elements (Levinson, 1974).

There are isolated sample anomalies which do not produce an obvious pattern outside the four areas described above. Some can be related to known minor mineralisation, and others identified fault structures. As the incidence of artificial contaminants and high content of Sn is small, it is concluded that high metal values in isolated samples reflect the presence of local minor mineralisation. A table of anomalous stream sediment sites is given in Appendix 2.

In addition to the analysis of sediments and panned concentrates 278 samples of surface waters were analysed for fluoride (Figure 12). The resulting map of the data shows that the higher fluoride values have a tendency to be associated with the recognised mineralisation at Cold Keld, River Eden, and Fossdale. Waters from two adjacent streams flowing from Rise Hill into the River Dee [370 487] also contain fluoride in the range $0.05-0.14 \mu g/ml$ as do two samples in the Gayle Beck drainage [378 480]. Neither of these very localised occurrences can be attributed to mapped geological features. The stream draining the area of Mossdale Head, where fluorite is observed in outcrop (location 16 in Table 1), contains only average amounts of fluoride.

Soil survey of Tow Scar area

In the soil survey undertaken at Tow Scar 180 samples were collected along traverse lines (Figure 14) and analysed for Cu, Pb, Zn and Ba. Organic content (losson-ignition) and pH values were also determined in order to examine any possible correlation with element distribution. A small number of deep samples were taken by means of a mechanical auger from the areas of peat in an attempt to obtain material from close to bedrock and to compare these analytical data with other soil data. The data are presented in the form of contoured maps (Figure 15). Soil development in the area sampled is variable, though generally poor. In a number of areas there is a thick development of peat.

Additional information was obtained from a study of panchromatic aerial photography of Tow Scar and the adjacent areas flown in 1969. Particular attention was paid to the recognition of fractures and joint patterns.

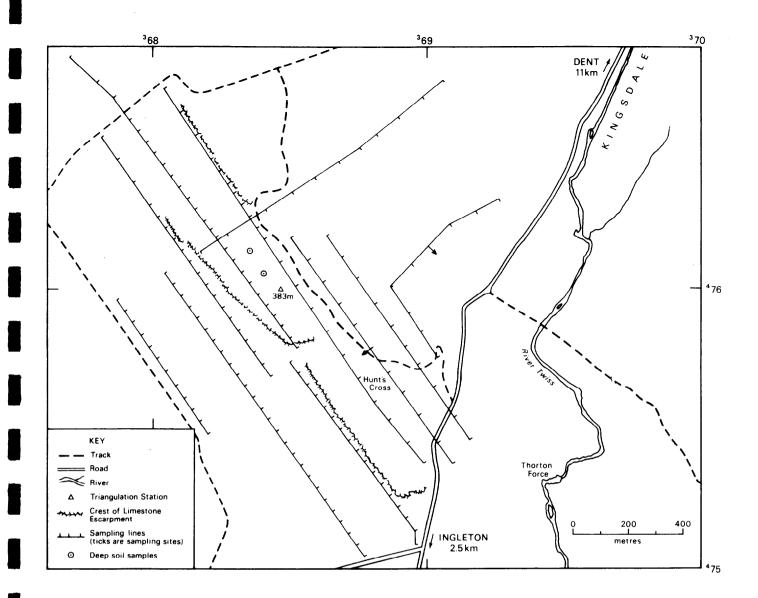

Soil geochemistry

Copper The highest values recorded (>75 ppm) are in three areas all of which lie along a NW trending zone coinciding with the Tow Scar feature and extending to Hunt's Cross in the southeast. The maximum value is 750 ppm Cu and this occurs just below the crest of Tow Scar at [36819 47601]. Values for copper tend to diminish both to the NE and to the SW, enhanced copper values seemingly being restricted to the block of Great Scar Limestone bounded by two main components of the North Craven Fault system. A distribution of values in a NE trend in the southeast end of the area probably reflects the effects of a NE fault situated south of Hunt's Cross. The distribution of low copper values (up to 15 ppm) within the generally anomalous zone coincides with the more extensive patches of peat developed on the limestone.

Lead High values of lead are rather more widespread than those of copper. The main NW trend is again apparent with some lower values possibly reflecting the variability in the thickness of the peat cover. Some high values of c.300 ppm Pb are located on the limestone pavement area to the NE. As with the copper there is no evidence of enhanced values on the downthrown side of the North Craven Fault. There are a number of results in excess of 2000 ppm Pb from sites at [36819 47624], [36824 47607] and [36838 47598].

Zinc Values in excess of 1250 ppm Zn are restricted to small areas generally coincident with those relating to the copper values. Like the distribution of the copper there is no evidence of enhanced zinc values beyond the fault bounded block of Great Scar Limestone exposed on Tow Scar. Several soils, from [36819 47624] (a site also high in barium and lead) and [36858 47593], contain >5000 ppm Zn.

t i

Barium Unlike the previous elements considered, some higher values for barium have been recorded from the topographically lower ground to the SW of Tow Scar from soils overlying rocks of Upper Carboniferous age. It is possible that these areas of high values relate to the poorly developed drainage away from Tow Scar. The maximum barium value (4400 ppm Ba) is associated with high lead and zinc at [36819 47624]. At [36824 47607] a value of 3000 ppm Ba is recorded at a site also high in lead.

pH The pH was measured in order to determine if there was any pH control on the distribution of heavy metals. A comparison of the pH contour map with the element contour maps suggests no spatial correlation. Contrary to what might be expected, the soils on the sandstone below Tow Scar are more alkaline than the soils on the limestone. This would arise from the development of peaty gleys on glacial material and the high organic content of some of the thin poorly developed soils on the limestone plateau.

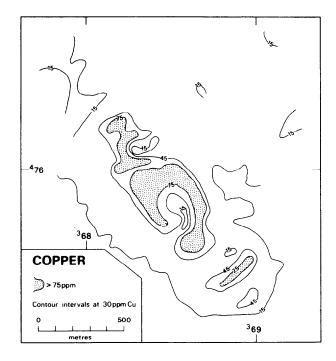

Organic content The percentage loss in weight of soils baked in a furnance at 400° C for 20 hrs is used as an indication of the organic content of the soils. It was determined in order to establish if there was any significant accumulation of metals by organic-rich soils. A comparison of the organic content contour map with the element contour maps shows no clear spatial correlation. It is suggested that the high organic contents of soils on the limestone plateau is responsible for making the soils of this area less alkaline. High organic values indicated on Figure 15 do not necessarily indicate peat development as the samples analysed were normally obtained from levels below the organic-rich surface horizons.

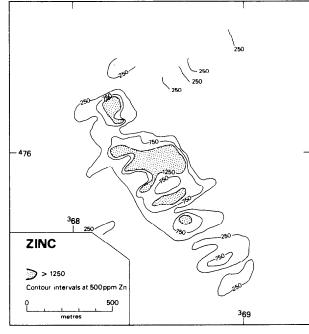

Deep soil samples At two sites shown on Figure 14 deep soil samples were collected in addition to surface samples (i.e. <1 metre) using a Cobra power auger. These sites were located in an area of thick peat development where low Cu, Pb, Ba and Zn had been recorded in samples collected by hand auger. At the most northerly site the power auger reached a depth of 5 m, where sandstone boulders prevented deeper sampling. No significant chemical differences were found between deep and surface soils at this locality though it is not clear how far above the limestone bedrock the deep sample was collected. Bedrock was reached within 3 m at the most southerly site, and although Cu and Pb did not show variation with depth, Zn increased from 80 ppm at the surface to 340 ppm just above bedrock. Barium was not determined on these samples.

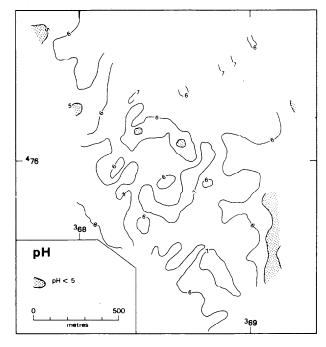

Aerial photography

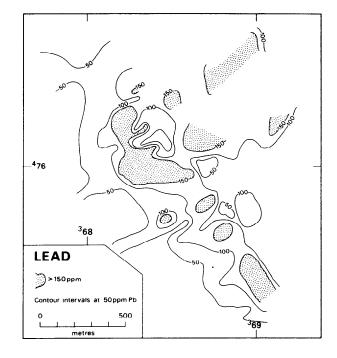

Examination of the aerial photographs shows the much jointed and faulted nature of the limestone outcrop in the vicinity of Tow Scar (Figure 16). The two main components of the Craven Fault structure are easily observed together with a number of associated subsidiary

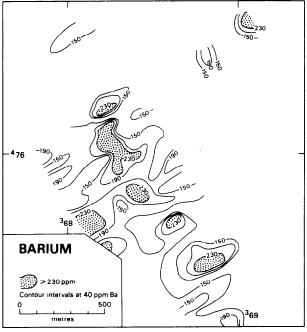

•

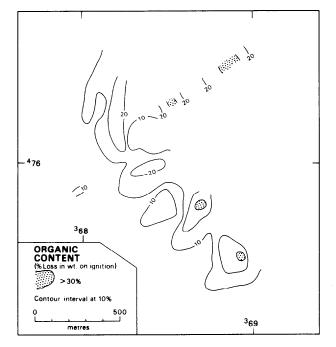

Figure 15 Contour maps of Tow Scar soil geochemistry data.

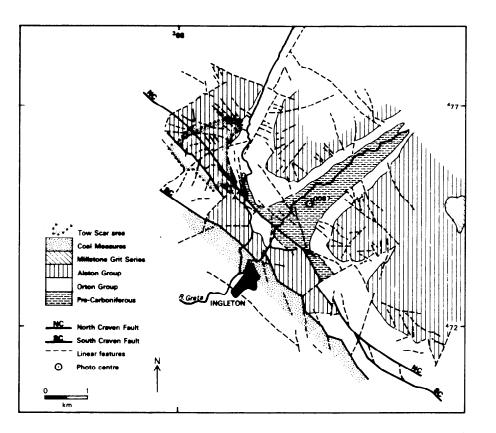

Figure 16 Geology and structure of the Tow Scar area, drawn from aerial photographs.

faults. The majority of the short linear features are undoubtedly representative of the main jointing patterns observed on the limestone pavements, their lateral extent in many instances seen to be restricted to the outcrop of the limestone. Variations in the observed density of jointing are directly related to the degree of peat development on the limestone.

Field observations and discussion of results

The soil geochemistry results indicated many sites of high base metal content in an area where no metalliferous mineralisation had been reported. An evalution of these data therefore warranted a more detailed examination of the geology of Tow Scar.

The most noticeable effect of faulting on Tow Scar is the change in the attitude of the beds of limestone from the gentle regional dip to the NNW to dips in excess of 50° towards the fault plane (i.e. to the SW). Lithologically the outcrop is reasonably uniform: massively bedded pale grey limestone with a patchily developed dolomitic facies. In one relatively small area at the northwestern end of the crop the limestone contains irregular nodules and lenses of highly siliceous material which characteristically weather to a honeycomb texture. These are aligned parallel to the lithological banding and are traceable in a zone some 45 m along strike and 5 m in width. This zone is associated with a large number of ramifying veins composed of essential calcite accompanied by chalcopyrite and copper carbonates. Elsewhere on the outcrop veining of any type is less common, but where seen it consists of calcite (frequently iron stained). The predominant direction of these veins is 330-360° but occasional other directions have been noted. A single calcite vein traceable in a NNW direction over 10-15 m attains a maximum width of 30 cm, and contains chalcopyrite. Dakyns and others (1890) refer to a fault that passes by Hunt's Cross -

"...probably without much 'throw', but marked by much dun limestone with calcite along its course".

The area of maximum observed vein occurrence 300 m NW of the triangulation station on Tow Scar coincides with high values of Cu, Pb, Zn and Ba in the soils.

The area of interest at Tow Scar, with the high soil values for Cu, Pb and Zn, is seen from the published geological map to coincide with a segment of Great Scar Limestone preserved between two main fault elements of the North Craven fault zone. The distribution of the anomalous values seems to be associated with a number of subsidiary faults which trend approximately 055°. It can also be ascertained from the aerial photography that a further area to the east, some 3 km by 1 km with similar structural controls (i.e. Great Scar Limestone bounded by major faults), can be identified and such an area presents itself as a potential target for further investigation.

CONCLUSIONS AND RECOMMENDATIONS

The drainage basin reconnaissance has not indicated any major new mineralisation. The levels of copper, lead, zinc and barium in the stream sediments and panned concentrates are similar to the values expected in such a sedimentary environment. In a reconnaissance exercise in the Lower Carboniferous area of Northumberland, the means and ranges of these elements in the stream sediments are particularly comparable (Bateson and others, 1983).

The areas showing anomalous values for one or more elements can be related in most instances to known mineralised faults. Of the exceptions, part of Area 1 (see Figure 13) may be a reflection of the more variable lithologies of the Lower Palaeozoic and the observed mineralisation associated with the Dent Fault. The anomalies in the remainder of Area 1 and Areas 2 and 3 probably represent the southern margin of the extensive mineralisation of the upper part of Swaledale. The grouping of anomalous values in Area 4 located in a largely Carboniferous environment is not explained from data indicated on any published geological map. However, in this area it is probable that the higher metal values are related to the observed minor mineralisation

and the presence of Silurian sediments in the lower part of the drainage basin.

Soil data obtained from Tow Scar indicates that part of the North Craven Fault system in this area may have acted as a passageway for mineralising fluids, the metals finding a suitable host in the Great Scar Limestone. It is of interest to note the relationship of the best developed mineralisation at Tow Scar with the limited occurrence of cherty nodules in the outcrop of the Great Scar Limestone.

The significance of the results from Tow Scar is twofold. Firstly the mineralisation was located as a result of a botanical observation and secondly it indicates a possibility of mineralisation adjacent to the North Craven Fault system to the east in areas of similar geological conditions.

The area surveyed cannot be recommended for further mineral exploration with any prospect of discovering economic deposits.

ACKNOWLEDGEMENTS

The authors thank Mr. M. McGlashan and Mr. G. Hewson, who collected most of the drainage and soil samples. The figures have been drawn by the Drawing Office, IGS Keyworth; the text prepared and formatted by Ms L. K. Waterhouse, Editorial and Publication Unit, IGS Keyworth.

APPENDIX 1 Location and analytical data for drainage basin reconnaissance.

 Table 1
 Stream sediment and water samples.

Table of locational and analytical data for stream sediments and waters. For sediments the concentrations are in ppm; for waters $\mu g/ml$. Absent data are indicated by -1.00.

Table 2 Panned concentrates

Table of panned concentrate data for barium, lead, zinc, copper, manganese and tin. With the exception of sample numbers 3330 and 3331, for locational data refer to Table 1. Concentrations in ppm. Absent data are shown as 0 and results below the detection limit are given as 1.

 in the element column indicates an anomalous level of that element present in the stream sediment sample: Ba >950 ppm
 Pb >80 ppm
 Zn >450 ppm
 Cu >28 ppm

* sample suspected of being contaminated (deduced from high Sn found in panned concetrate from the same site and examination of concentrate sample)
