7 **ABSTRACT**

8 Exceptional exposures of four, precisely-dated, Middle Jurassic to Early Cretaceous,
9 silicic volcanic centers and their plutonic equivalents in Hong Kong have provided an excellent
10 opportunity to examine close connections in time and space between magma chambers and their
11 overlying calderas. Here, we describe a ~14 km crustal section through a collapsed caldera in
12 southeastern Hong Kong where the intracaldera fill suggests that the magmatic discharge was of
13 supereruption scale. The main subvolcanic components that link a magma chamber with surface
14 are revealed by well-established field relationships, supplemented by high precision
15 geochronology, whole-rock geochemistry, and geophysical data. Exposures and outcrop patterns
16 reveal kilometer-scale caldera subsidence and evidence of the simultaneous evacuation of
17 hundreds of cubic kilometers of high-silica rhyolite magma through dike-like conduits from a
18 shallow subcrustal reservoir. The resultant volcanotectonic depression, within which is preserved
19 a single cooling unit of massively columnar-jointed densely welded tuff (High Island tuff), is
20 interpreted to form part of a larger tilted Early Cretaceous nested caldera complex. The High
21 Island eruption signaled the end of a 24 Myr-period of voluminous, pulsed Middle Jurassic to

22 Early Cretaceous silicic magmatism in the Hong Kong region characterized by four discrete
23 ignimbrite ‘flare-ups’.

24 **1. Introduction**

25 Primary investigative methods of the geometry of magmatic plumbing systems beneath
26 large silicic calderas generally concentrate on geophysical measurements of giant caldera
27 complexes in repose [e.g., *Christiansen et al.*, 2007], geochemical and structural studies of
28 exhumed subvolcanic magma chambers [e.g., *Kokelaar and Moore*, 2006], and detailed
29 petrologic studies of crystals and melt inclusions in eruptive materials [e.g., *Davidson et al.*,
30 2007]. Descriptions of near-continuous upper crustal sections, which allow direct observations of
31 the architecture of these systems from the floor of the magma chamber to the top of the exposed
32 caldera infill, are relatively uncommon [e.g., *Quick et al.*, 2009]. Here, we describe a ~14 km
33 crustal section through a tilted Early Cretaceous nested caldera complex in southeastern Hong
34 Kong (herein the Special Administrative Region), whose internal architecture has been exhumed
35 through a fortuitous combination of gentle crustal warping and erosion. The relationships of the
36 caldera and its subvolcanic plumbing have been mapped and further deduced from geological,
37 geochemical and geophysical evidence and established within the context of overlapping Early
38 Cretaceous volcanic–plutonic centers. This paper lays the foundation for upcoming detailed
39 petrologic investigations by one of us (DLKT), and particularly specific crystal studies using
40 micro-analytical techniques, of these overlapping magmatic centers. This may help to address
41 current controversies about the evolution of large silicic magma systems [e.g., *Coleman et al.*,
42 2004; *Glazner et al.*, 2004; *Gray et al.*, 2008; *Reid et al.*, 2011] and their volcanic–plutonic
43 connections [e.g., *Bachmann et al.*, 2007; *Kennedy and Stix*, 2007; *John et al.*, 2008].

44 **2. Geologic Setting**

45 Over 80% of the rocks in Hong Kong are Middle Jurassic to Early Cretaceous (Early
46 Yanshanian 190–140 Ma) volcanic–plutonic associations. These belong to four main episodes:
47 165–160 Ma, 148–146 Ma, 143 Ma and 141 Ma, constrained by 44 high-precision U-Pb single
48 crystal zircon ages [*Campbell and Sewell, 1997; Davis et al., 1997, Campbell et al., 2007; Sewell*
49 *et al., 2012*] and approximately 1000 whole-rock major and trace element analyses [*Sewell and*
50 *Campbell, 1997; Figure 1*]. The episodes are consistent with regional-scale ignimbrite ‘flare-ups’
51 (used here informally to reflect magmatic episodes of very variable duration and lateral extent).
52 The magmatic events in Hong Kong are only a small part of the very much larger zone of Early
53 Yanshanian magmatism that occurred at the same time in southeastern China [*Li and Li, 2007*].
54 High precision U-Pb zircon ages from Guangdong Province suggest that magmatic episodes
55 were of similar timing and duration to Hong Kong. Accordingly, Hong Kong is ideally placed to
56 constrain the episodic nature of magmatism within the zone as a whole.

57 The two Jurassic (165–160 Ma, 148–146 Ma) ‘flare-ups’ and their volcanic and
58 subvolcanic expressions are spatially and temporally well-defined in northwestern and central
59 Hong Kong and include volcanic–plutonic caldera complexes on Lantau Island and in the central
60 New Territories (Figure 1). They are composed of: mainly high-K calcalkaline dacite to rhyolite
61 lapilli to coarse ash crystal tuffs; and related I-type granitoid and A-type granite (65–72 wt%
62 SiO₂) plutons [*Sewell et al., 1992; Campbell and Sewell, 1997; Sewell and Campbell, 1997*].
63 Nearly complete, NE- and E-elongated calderas, delineated by ring faults and ring-like
64 intrusions, reflect the strong influence of NE-trending regional faults on the distribution and loci
65 of two Jurassic volcanic centers [Figure 1, *Campbell and Sewell, 1997*].

66 The two Early Cretaceous (143 Ma, 141 Ma) ‘flare-ups’ and their volcanic and
67 subvolcanic expressions spatially overlap in southeastern Hong Kong. They include volcanic–

68 plutonic caldera complexes in the eastern New Territories and southern Hong Kong Island
69 (Figure 1). These are dominated by high-K calcalkaline to shoshonitic high silica rhyolite (>75
70 wt% SiO₂), welded, fine ash vitric tuff, with subordinate dacite to rhyolite coarse ash crystal tuff,
71 and minor trachydacite to rhyolite lava [*Sewell and Campbell, 1997*]. Compositional-related and
72 broadly coeval age-related intrusions comprise I-type granites, and A-type dikes and stocks of
73 quartz monzonite [*Campbell and Sewell, 1997; Davis et al., 1997; Sewell and Campbell, 1997;*
74 *Sewell et al., 2012*]. In contrast to the Jurassic calderas, the preservation of the Early Cretaceous
75 calderas is more incomplete; they have northerly elongations consistent with movement on E-
76 and N-trending faults.

77 **3. Early Cretaceous Volcanic–Plutonic Coeval Episodes**

78 In the eastern New Territories, volcanic and sedimentary rocks belonging to the two Early
79 Cretaceous ‘flare-ups’ dip gently to the east at 10–30°. They are underlain in the west by
80 subvolcanic granite plutons and quartz monzonite stocks of equivalent age and composition
81 [Figure 2, *Sewell et al., 2000*]. General petrologic characteristics of the Early Cretaceous
82 volcanic and plutonic rocks are given in Table 2.

83 **3.1 143 Ma Volcanic–Plutonic Episode**

84 The stratigraphy of the 143 Ma ‘flare-up’ has been uncertain due to subsequent caldera
85 development (the 141 Ma ‘flare-up’), and correlation of units on textural and compositional
86 grounds is problematic. Earlier interpretations suggested broadly coeval eruptions from two
87 separate calderas represented by: a dacite-rhyolite assemblage (‘rhyolitic subgroup’) from the
88 Long Harbour Caldera and Sai Kung Caldera in eastern Kowloon, and a trachyte-rhyolite
89 assemblage (‘trachytic subgroup’) from a presumed strongly dismembered, incomplete, ‘caldera’
90 centered on Hong Kong Island [Ap Lei Chau Caldera, *Campbell and Sewell, 1997*]. Folding of

91 the trachyte-rhyolite assemblage was interpreted to have been caused by granite intrusion [*Sewell*
92 *et al.*, 2000]. The calderas are underlain by a NE-oriented ellipsoidal 143 Ma pluton north of
93 Kowloon [*Sewell et al.*, 2012], and a subcircular 143 Ma pluton centered on southern Lantau
94 Island [*Davis et al.*, 1997; Figure 2].

95 However, we have now used the TiO₂ versus Zr plot [Figure 3A, cf. *Campbell and*
96 *Sewell*, 1997, see Datasets DS01 and DS02] to reconstruct the pre-collapse configuration and the
97 original stratigraphy for the 143 Ma ‘flare-up’ (Figure 4). This suggests that earlier eruptions
98 were dominated by voluminous, weakly zoned dacite–rhyolite (66–75 wt% SiO₂) coarse ash
99 crystal tuff (40–50% crystals), whereas later eruptions were dominated by trachydacite to high
100 silica rhyolite (63–77 wt% SiO₂) crystal-bearing fine ash vitric tuff. *Sewell and Campbell* [1997]
101 originally assigned these rocks to separate phases (Phases 3 and 4) of the 143 Ma magmatic
102 episode based on K₂O vs. SiO₂ and Ti vs. Zr relationships. Penultimate eruptions culminated in a
103 strongly welded fine ash vitric tuff. A 170 m-thick volcanoclastic unit overlying the welded tuff
104 represents the final accumulation in a volcanotectonic depression following the caldera-forming
105 event. The stratigraphic interpretation for the 143 Ma ‘flare-up’ is corroborated by
106 geochronological and geochemical studies of the Lantau Caldera on Lantau Island [Figure 1,
107 *Campbell et al.*, 2007]. This caldera therefore preserves a condensed record of Middle Jurassic to
108 Early Cretaceous ‘flare-ups’, including a 200 m-thick stratigraphic sequence with very similar
109 age and compositional characteristics to the 143 Ma ‘flare-up’ from eastern New Territories and
110 southern Hong Kong Island.

111 In parallel with the 143 Ma volcanic sequences, the underlying 143 Ma plutons are also
112 strongly dismembered due to the subsequent 141 Ma caldera development. This is most vividly
113 illustrated by the NE-oriented ellipsoidal 143 Ma pluton north of Kowloon (Figure 2) which has

114 been offset, apparently dextrally, by approximately 4 km, along a prominent NE-trending fault
115 marked by a 141 Ma quartz monzonite dike (Wong Chuk Fault – see below). In addition to
116 radiometric ages and spatial associations, whole-rock geochemical relationships [*Campbell and*
117 *Sewell, 1997; Sewell and Campbell, 1997*] demonstrate a genetic link between the 143 Ma
118 plutonic and volcanic rocks.

119 **3.2 141 Ma Volcanic–Plutonic Episode**

120 The first expression of the 141 Ma ‘flare-up’ appears to have been extrusion of flow-
121 banded trachydacite and eruption of rhyolite welded tuff on 143 Ma volcanic materials locally
122 from conduits in Clear Water Bay [*Sewell et al., 2012*]. This was followed by eruption of
123 rhyolite lava and tuff from conduits in the eastern New Territories [*Sewell et al., 2000*].
124 Subsequently, a caldera (High Island Caldera, Figure 2) developed during eruption and
125 emplacement of the High Island tuff. The northern and southern boundaries of the High Island
126 Caldera were previously delimited on the basis of E-trending and NW-trending faults, but the
127 eastern and western boundaries were not identified [*Campbell and Sewell, 1997*]. The High
128 Island tuff, comprising a single cooling unit of compositionally uniform, high-silica rhyolite
129 (>75 wt% SiO₂) crystal-bearing fine ash vitric tuff [Figure 3B, cf. *Campbell and Sewell, 1997*;
130 Figure 4], is non-welded to partly-welded at its base [*Tam and Chan, 1983*], grading rapidly
131 upward over 30 m into densely welded tuff. The densely welded tuff (Figure 5A) is characterized
132 by spectacularly well-developed columnar jointing, with column diameters up to 2 m (Figure 5B)
133 and observed vertical extents of 30 m and probably more. The base of the High Island tuff rests
134 on a 35 m-thick volcanoclastic unit characterized by tuff breccia, tuffaceous sandstone and
135 mudstone [*Strange et al., 1990, Figure 5C*]. An outlier of 141 Ma ‘flare-up’ is preserved
136 approximately 40 km to the southwest within the Lantau Caldera [*Campbell et al., 2007*]. This

137 outlier consists of a 230 m-thick sequence of welded tuff, flow-banded rhyolite, and tuff breccia,
138 resting on an 80 m-thick volcanoclastic unit which separates the 141 Ma volcanic assemblage
139 from the underlying 143 Ma volcanic assemblage (Figure 4).

140 The medium-grained 141 Ma granite pluton centered in Kowloon is capped along its
141 eastern boundary by fine-grained granite which has intruded the overlying 143 Ma volcanic
142 sequence (Figure 2). The fine-grained granite, containing miarolitic cavities, is locally strongly
143 greisenized and mineralized at its contact with volcanic rocks. The coeval NE- to E-trending
144 quartz monzonite to monzogranite dikes approximate the northern and southern boundaries of
145 the medium-grained granite pluton (Figure 2).

146 In northern Kowloon, the dikes commonly occur as broad (10 to 100 m wide) composite
147 (quartz monzonite to porphyritic monzogranite) intrusions. These amalgamate eastwards into
148 stocks of feldspar porphyry which, in turn, grade eastward into strongly flow-banded 141 Ma
149 rhyolite lava and tuff [Addison, 1986]. On Harker diagrams [Figure 6, cf. Sewell and Campbell,
150 1997], these plutonic and volcanic rocks display a comagmatic fractionation trend from
151 dominantly intermediate compositions in the west to highly silicic compositions in the east.

152 In southern Hong Kong Island and on Lamma Island, magmatically foliated quartz
153 monzonite to monzogranite stocks and dikes occur as discontinuous E- to NE-trending
154 intrusions. These can be traced eastward through the 143 Ma volcanic sequence into the basal
155 portion of the 141 Ma volcanic sequence (Figure 2), where the monzonitic bodies are closely
156 associated with volcanic conduit materials, including polymictic tuff breccia [Strange *et al.*,
157 1990; Figure 5D]. Field exposures in southeast Hong Kong Island, reveal that monzonitic stocks
158 and dikes are intruded by granite very similar in composition to the pluton centered on Kowloon.
159 This observation is consistent with U-Pb zircon geochronology [Davis *et al.*, 1997; Sewell *et al.*,

160 2012] which suggests that the granite pluton centered on Kowloon (140.4 ± 0.2 Ma) is slightly
161 younger than the monzonitic intrusions (140.6 ± 0.3 Ma). Marine boreholes and surface
162 exposures on small islands immediately west of Hong Kong Island reveal that most of the
163 offshore area to the north of Lamma Island and to the west of Hong Kong Island is underlain by
164 quartz monzonite. Quartz monzonite recovered from the boreholes displays mesocumulate
165 texture and in general, is compositionally more primitive (59–63 wt% SiO₂) than quartz
166 monzonite exposed farther east (66–68 wt% SiO₂, see Dataset DS03). On Harker diagrams
167 (Figure 6), the quartz monzonite to monzogranite stocks and dikes lie on a fractionation lineage
168 related to 141 Ma volcanic rocks exposed farther east.

169 Coeval mafic enclaves have been reported in the 141 Ma monzogranite from Lamma
170 Island [*Strange and Shaw*, 1986; *Sewell et al.*, 2000; Figure 5E]. These high K, low Ti,
171 shoshonitic monzodiorite enclaves are of similar composition to mafic dikes that intrude the
172 High Island tuff in eastern New Territories [*Sewell et al.*, 2000, Figure 5F].

173 **4. Early Cretaceous Tectonomagmatic Structures**

174 **4.1 Tectonomagmatic Structures Revealed by Geophysical Data**

175 Regional gravity and marine magnetic surveys carried out by the Hong Kong
176 Government [*Electronic and Geophysical Services Ltd.*, 1991; *Busby et al.*, 1992; *Fletcher et al.*,
177 2000; *Sewell et al.*, 2000] have revealed the continuity and depth of structures that influenced
178 Early Cretaceous magmatism beneath Hong Kong. Recognition of these structures is based on
179 the coincidence of gravity and magnetic anomalies with tabular magmatic bodies, particularly
180 the monzonitic dikes.

181 Gravity models developed for Hong Kong [*Fletcher et al.*, 1997] have included the
182 application of the Euler deconvolution technique [*Reid et al.*, 1990] to interpret basement

183 structures. The technique provides an indication of source geometry and depth from gravity data
184 without the need for prior knowledge of structures or reference to physical properties of the
185 rocks. However, the solutions depend on sufficient density contrasts in the structures to generate
186 anomaly gradients. Euler solutions calculated from Hong Kong-wide Bouguer gravity data
187 (Figure 7A) reveal linear, arcuate, and sigmoidal anomalies. Some can be directly linked with
188 faults and caldera boundaries mapped at the surface; others are interpreted as deeper structures
189 without known surface expression [Fletcher *et al.*, 1997]. Of particular interest are E- and N-
190 trending anomalies with solution depths from 1 to 8 km which are concentrated mainly in eastern
191 offshore areas (SI 1, Figure 7A). A major structural boundary is also suggested by shallow depth
192 solutions west of Lamma Island which separate dominantly linear anomalies in the north and east
193 from mainly arcuate and sigmoidal anomalies in the west and south (Figure 7A). Linear
194 anomalies that vary in length between 2 and 10 km, and are up to 500 m wide, are thought to
195 correspond to faults in the uppermost part of the middle crust and the upper crust.

196 The magnetic anomaly map [Fletcher *et al.*, 2000; Sewell *et al.*, 2000] for eastern and
197 southern Hong Kong waters (based on over 1000 line-kilometers of marine magnetic data
198 profiles) shows several lineaments that represent the offshore continuation of mapped faults
199 (Figure 7A). Additionally, several magnetic lineaments which align with Euler anomalies appear
200 not to have known onshore fault equivalents (e.g., N-trending structures in easternmost waters,
201 and E-trending structures near Sai Kung). Offshore quartz monzonite bodies, proven by marine
202 drilling and undersea tunnel excavation [Fletcher *et al.*, 2000], generally define magnetic ridges.
203 In southwestern Hong Kong, the magnetic ridges correlate with onshore quartz monzonite
204 intrusions along faults and help to delineate caldera-related structures. A prominent E–W-

205 trending magnetic ridge immediately to the southeast of Hong Kong Island has been interpreted
206 to reflect a quartz monzonite intrusion [*Fletcher et al.*, 2000].

207 Magnetic anomalies in the offshore area to the northwest of Lamma Island suggest the
208 existence of a WNW-ESE structural boundary separating magnetically neutral granitic rocks in
209 the north and east from magnetically positive granitic rocks in the south [*Fletcher et al.*, 2000].
210 Magnetic ridges interpreted as quartz monzonite intrusions can be traced for 12 km
211 southwestward from west Kowloon where they appear to terminate against magnetically positive
212 granitic rocks near Lantau Island. Immediately to the west and north of Lamma Island, two
213 dipolar, extremely strong magnetic anomalies (>3000 nT) with positive values in the south and
214 negative values in the north have been interpreted as steeply plunging, highly magnetic basic
215 plugs within 250 m of the seafloor [*Fletcher et al.*, 2000].

216 Field and geophysical observations have led to recognition that the structural
217 configuration in eastern and southern Hong Kong represents a combination of both depth and
218 lateral dimensions of a large collapse caldera system. Due to the prevailing dip of the strata, the
219 depth dimension is expressed largely as a lateral dimension and this explains the variable
220 orientation of caldera-bounding faults and related structures. The lateral dimension is
221 foreshortened due to the dominance of the depth dimension. Consequently, the apparent sinistral
222 and dextral offsets of caldera-bounding faults and related structures have a significant vertical
223 component related to the collapse phase of caldera development.

224 **4.2 Caldera-bounding faults and related structures**

225 Several faults are interpreted as having strongly influenced caldera development, and
226 having served as magma conduits, during the two Early Cretaceous ‘flare-ups’ [*Campbell and*

227 *Sewell, 1997*]. These include the Tolo Channel, Chek Keng, Wong Chuk, Tin Ha Shan, Jordan
228 Valley Tiu Keng Leng, and Sheung Sze Mun faults (Figure 2).

229 (a) The NE-trending Tolo Channel Fault (Figure 2) approximates the boundary between the
230 Jurassic and Cretaceous volcanic–plutonic associations (Figure 1). On the magnetic anomaly
231 map for western Victoria Harbour [*Sewell et al., 2000*], the fault marks the abrupt termination of
232 a major ENE-trending, Late Jurassic dike swarm, most extensively developed on eastern Lantau
233 island.

234 (b) The E- to ENE-trending Chek Keng Fault (Figure 2) is characterized by sporadic
235 intrusions of quartz monzonite to monzogranite and has previously been interpreted as marking
236 the E-W boundary between the Long Harbour ‘caldera’ and the High Island ‘caldera’ [*Strange et*
237 *al., 1990; Campbell and Sewell, 1997, Figure 1*]. Farther west, the fault displays a southwestward
238 bend and eventually coincides with monzonitic dikes which intrude granite in the central New
239 Territories. The fault marks the northern boundary of a major conduit that fed rhyolite lava
240 belonging to the 141 Ma ‘flare-up’, whereas in the east it is terminated abruptly by a N-trending
241 fault. The easterly-dipping 143 Ma volcanic sequences on either side of the fault have been
242 offset, apparently dextrally and probably vertically to a significant extent, by approximately 10
243 km.

244 (c) The NE-trending Wong Chuk Fault (Figure 2) was previously thought to mark the
245 northwestern boundary of the Sai Kung ‘caldera’ [*Sewell et al., 2000*]. It is characterized for
246 most of its 8 km length by a 100 m-wide quartz monzonite intrusion which marks the southern
247 boundary to the 141 Ma rhyolite lava conduit described above (opposite to the Chek Keng Fault).
248 In the southwest, the Wong Chuk Fault bifurcates, one segment of which continues linearly to
249 coincide with a zone of numerous NE-trending monzonitic dikes, and the other which bends to

250 the south, and then to the southwest, before terminating in the 141 Ma granite plutons centered
251 on Kowloon.

252 (d) The E- to ENE-trending Tin Ha Shan Fault (Figure 2) is characterized in eastern
253 Kowloon by a 1400 m-wide volcanic conduit infilled with block-rich pyroclastic material and
254 dikes of quartz monzonite to monzogranite. On Hong Kong Island, the fault coincides with a
255 discontinuous tabular NE-trending quartz monzonite to monzonite intrusion which passes
256 through central Hong Kong Island.

257 (e) The NE-trending Jordan Valley Fault (Figure 2) was previously thought to mark the
258 southeastern boundary of the Sai Kung ‘caldera’ and was inferred [Sewell *et al.*, 2000] to link up
259 with sporadic monzonite intrusions farther northeast. We now consider that a WNW-trending
260 fault mapped through High Island Reservoir [Strange *et al.*, 1990; Sewell *et al.*, 2000], makes a
261 southwestward bend to coincide with the Jordan Valley Fault. The contact between the High
262 Island tuff and underlying rhyolite lava unit on either side of the fault has been offset, apparently
263 dextrally, by approximately 3 km, and provides compelling evidence that this fault is the
264 southeastern bounding fault of the caldera.

265 (f) The NE-trending Tiu Keng Leng Fault (Figure 2) is associated with a NE-trending quartz
266 monzonite intrusion in eastern Kowloon [Geotechnical Control Office, 1986, 1989a, 1989b]. In
267 Sai Kung, the fault is inferred make a right angle bend to coincide with an E-trending offshore
268 magnetic lineament (see below). The fault is responsible for apparently sinistral offsets of the
269 volcanoclastic unit and the trachydacite lava unit belonging to the 143 Ma and 141 Ma ‘flare-
270 ups’, respectively.

271 (g) The ENE-trending Sheung Sze Mun Fault (Figure 2) is inferred to mark the southern
272 boundary of the Early Cretaceous volcanic–plutonic association in Hong Kong. It is defined by a

273 strong magnetic ridge interpreted as a quartz monzonite intrusion in the offshore channel
274 immediately to the southeast of Hong Kong Island. Granitic rocks on islands to the south of the
275 channel have been dated as belonging to the 146 Ma ‘flare-up’ [Sewell *et al.*, 2012].

276 **5. Tilted Nested Caldera Complex**

277 Available geological, geochemical and geophysical evidence show that southeastern
278 Hong Kong, comprising mainly Early Cretaceous granitic rocks in the southwest and volcanic
279 rocks in the northeast, and bounded by the Tolo Channel Fault in the north and the ENE-trending
280 Sheung Sze Mun Fault in the south, has been tilted eastward by up to 30°. This has resulted in
281 near continuous exposure for 30 km (east to west) revealing a vertical crustal section
282 approximately 14 km thick, from the floor of the magma chamber to the top of the exposed
283 caldera infill (Figure 7B). The caldera complex is dominated by the High Island Caldera and its
284 comagmatic subvolcanic intrusions. These are nested within a 143 Ma volcanic–plutonic
285 assemblage, representing an earlier caldera complex, which was strongly dismembered during
286 the subsequent 141 Ma ‘flare-up’ and caldera collapse.

287 The southern and northern boundaries of the High Island Caldera are delimited by tabular
288 quartz monzonite to monzogranite intrusions along faults, which fed trachydacite-rhyolite domes
289 and volcanic conduits exposed in easternmost outcrops. The eastern boundary of the caldera is
290 represented by N–S trending magnetic and gravity (Euler) lineaments which probably mark
291 intrusions along faults at depth. The western boundary, exposing a deeper crustal level, is
292 marked by NW- to N-trending mesocumulate-textured quartz monzonite to monzogranite
293 intrusions west of Hong Kong Island. These link with quartz monzonite to monzogranite dikes
294 from the central New Territories, and probably represent the residue of the evacuated magma
295 chamber.

296 We interpret the Chek Keng, Jordan Valley and Tiu Keng Leng faults associated with
297 monzonitic intrusions and with pronounced bends, as caldera collapse-related structures (Figure
298 7B). Kilometer-scale vertical subsidence is inferred along these faults on the basis of evidence
299 from: geochemical correlation of fault-bounded volcanic blocks comprising volcanic strata of the
300 143 Ma flare-up; offsets of mappable contacts; and thickness variations among the 141 Ma
301 volcanic units. The previously interpreted 143 Ma ‘calderas’ are now considered to belong to a
302 single 143 Ma caldera (redefined here as the Sai Kung Caldera). A relatively intact upper crustal
303 remnant of this caldera is preserved adjacent to the Tolo Channel Fault, along the northern
304 margin of the nested caldera complex (Figure 7B). This reveals an eastward-dipping (up to 30°
305 dip) layered sequence comprising the 143 Ma, 146 Ma, and 164 Ma volcanic successions. These
306 overlie older sedimentary rocks and are intruded at depth by 143 Ma plutons. Along the southern
307 margin of the nested caldera complex, the Sai Kung Caldera has been extensively dismembered
308 by subsequent collapse of the High Island Caldera and intrusion of 141 Ma plutons. The strongly
309 folded blocks of fine ash vitric tuff on Hong Kong Island, compared to the relatively intact tuff
310 blocks in eastern Kowloon, represent massive disruption and foundering of the 143 Ma volcanic
311 assemblage due to collapse of the subsequent High Island Caldera (Figure 7B). Asymmetric
312 block collapse of the caldera may have promoted the deep foundering of the 143 Ma volcanic
313 assemblage [cf. Questa Caldera, *Lipman*, 1983, see below]. Several mega-xenolithic blocks of
314 volcanic and plutonic material belonging to the 164 Ma magmatic episode also collapsed deeply
315 into the underlying magma chamber and are now enveloped by quartz monzonite and
316 monzogranite intrusions on the southern margin of the caldera complex.

317 Caldera-bounding faults delimited by quartz monzonite to monzogranite intrusions are
318 vestiges of the plumbing system related to the overlying High Island Caldera. They probably

319 served as major conduits for the evacuating 141 Ma magma chamber. Slightly more primitive,
320 mesocumulate-textured quartz monzonite stocks in the west, compared to the east, possibly
321 represent unerupted crystal-rich portions of the magma chamber. Coeval mafic enclaves in
322 associated monzogranite, combined with magnetic anomalies suggesting near surface mafic
323 intrusion, indicate involvement of mafic magma in the source. Abrupt changes in magnetic and
324 gravity patterns in the offshore area to the west of Lamma Island probably delineate the
325 southwestern limit of the nested caldera complex which also corresponds to its deepest level of
326 exposure. Reconstruction of the upper crustal geometry for southeastern Hong Kong (Figure 8A)
327 suggests that it represents a tilted cylinder-shaped nested caldera complex. This is made up of
328 many collapsed crustal blocks. Tilting of the nested caldera complex (Figure 8B) probably
329 occurred during, or immediately after, paroxysmal evacuation of the High Island tuff.

330 The 141 Ma granites centered on Kowloon most likely represent magmatic recharge of
331 the evacuated reservoir that fed the High Island tuff. Magmatic resurgence further deformed the
332 collapsed crustal blocks, particularly on southern Hong Kong Island. Subsequently, the Early
333 Cretaceous nested calderas and their subvolcanic plutons were uplifted and eroded to expose the
334 present crustal extent (Figure 8C).

335 **6. High Island Tuff Supereruption**

336 The compositionally uniform, densely welded, High Island tuff is considered to represent
337 the intracaldera fill of an immense eruption that signaled the end of Mesozoic silicic volcanic
338 activity in Hong Kong [*Strange et al.*, 1990; *Campbell and Sewell*, 1997; *Sewell et al.*, 2000]. A
339 colossal volume of pyroclastic material ponded and cooled within the depression. What remains
340 preserved is a single cooling unit of tuff with gigantic columnar joints (columns up to 2 m
341 diameter). Outflow and co-ignimbrite ash fall deposits from this eruption have now been

342 completely eroded, except for an uppermost 25-m thick fine ash tuff unit (141 Ma) within the
343 Lantau Caldera which may represent a preserved remnant of the outflow sheet. The High Island
344 tuff is interpreted as the erupted, highly differentiated upper portion of a large, shallow, zoned
345 quartz monzonite to high-silica granite magma body. Quartz monzonite dikes and stocks,
346 representing tapping of the crystal-rich portion of the magma chamber, were injected into the
347 main volcanic conduits at a late stage of the eruption. Some of these differentiated internally to
348 monzogranitic compositions as they ascended. Sporadic mafic dikes, possibly representing a
349 mafic underplate at depth, were intruded simultaneously with, or immediately after, the
350 emplacement of quartz monzonites, but reached higher levels, including the basal portion of the
351 still cooling High Island tuff. Resurgent activity, marked by the large 141 Ma granite body
352 centered on Kowloon, probably caused further deformation of collapsed 143 Ma crustal blocks.

353 **6.1 Eruptive Volume**

354 Estimates of the eruptive volume of the High Island tuff are necessarily speculative
355 owing to the virtual absence of deposits outside the known boundaries of the caldera, and
356 uncertainties over the amount of regional erosion. However, some rough estimates are possible,
357 even where only a remnant intracaldera fill deposit is preserved, based on knowledge of some
358 well-studied ignimbrites and ash-flow calderas [e.g., *Wilson, 2001; Lipman, 2007*]. The first
359 ingredient to establish is the average bulk density of the tuff. This can be done either by direct
360 measurement, or by calculation on the basis of whole-rock chemistry.

361 The saturated bulk density of the High Island tuff, measured in accordance with the
362 International Society for Rock Mechanics Suggested Methods [Brown, 1981], is 2560 kg m^{-3} ,
363 which is slightly higher than the range of values ($2000\text{--}2500 \text{ kg m}^{-3}$) normally quoted for welded
364 ignimbrites [*Mason et al., 2004*]. On the basis of whole-rock chemistry, the average bulk density

365 of the tuff is 2300 kg m^{-3} using the computer program 'KWare Magma' available from KWare-
366 Geological Software (<http://geodynamics.lanl.gov/Wohletz/Magma.htm>). We propose, therefore,
367 that the best estimate of the average bulk density for the High Island tuff lies midway between
368 these two end members at approximately 2430 kg m^{-3} . This is close to the average bulk density
369 (2450 kg m^{-3}) used by *Mason et al.* [2004] to compare the sizes of the largest known ignimbrite
370 deposits on Earth.

371 The minimum thickness of High Island tuff, measured from its basal contact with the
372 underlying rhyolite lava to its easternmost exposure, is about 1 km. However, fission track
373 thermochronometric data from neighbouring Guangdong Province [*Yi et al.*, 2009] suggests 3–6
374 km of regional unroofing since the Late Cretaceous. So this minimum thickness of intracaldera
375 ash flow deposit may be a considerable underestimate.

376 The structural boundaries of the High Island Caldera, delineated by quartz monzonite and
377 monzogranite dike intrusions, volcanic conduits, marked angular unconformities with underlying
378 units, mesobreccias, etc, are projected to form an ellipsoid in outline with a north-south long axis
379 of c.18 km. Based on a minimum thickness of intracaldera ash flow deposit of 1 km, and a
380 caldera diameter of 18 km, the estimated dense rock equivalent (DRE) intracaldera volume of the
381 High Island tuff is $\sim 250 \text{ km}^3$. *Lipman* [1984] proposed that the outflow deposit (O) volume is
382 approximately equivalent to the intracaldera ash flow deposit (I) volume. In a similar manner,
383 *Sparks and Walker* [1977] suggested that some outflow deposit volumes approximated the co-
384 ignimbrite ash fall deposit (A) volume. Assuming that the co-ignimbrite ash fall deposit for the
385 High Island eruption had an average dry bulk density of 700 kg m^{-3} (midpoint of the range (600–
386 800 kg m^{-3}) for fresh rhyolitic ash fallout [*Shipley and Sarna-Wojcicki*, 1982]), and scaling
387 against the estimated bulk density for welded ignimbrite, then the minimum volume of magma

388 erupted (I + O + A) is estimated as $\sim 570 \text{ km}^3$. This falls within the general definition of a
389 supereruption [e.g., *Mason et al.*, 2004].

390 **6.2 Western USA Cordillera and Southeastern China Analogs**

391 We consider that the Questa Caldera in northern New Mexico, USA, [*Lipman*, 1983;
392 *Johnson et al.*, 1989] represents a close analog of the High Island Caldera in terms of
393 topographic dimensions ($>15 \text{ km}$ diameter), volume ($>500 \text{ km}^3$) and high-SiO₂ composition (76–
394 78 wt%) of material erupted, collapse style, and the exposed volcanic–plutonic connections. The
395 26 Ma Questa Caldera developed above a shallow, quartz monzonite to granite magma body
396 undergoing extension along regional faults. The extensional tectonic setting is thought to have
397 influenced asymmetric collapse of the caldera during eruption of the Amalia Tuff, and intense
398 deformation and rotation of foundering crustal blocks. A shallow granite body is also thought to
399 represent a resurgent intrusion within the caldera.

400 Similarly, though on a smaller scale, we consider that the Searchlight pluton in the
401 Eldorado Mountains, Nevada, USA, [*Bachl et al.*, 2001] represents a compositional and
402 structural analog of the subvolcanic magma chamber that fed the High Island tuff.
403 Reconstruction of the Searchlight pluton from an interpreted tilted crustal section has unveiled a
404 fossil magma chamber. This comprises a lower basal unit of magmatically foliated quartz
405 monzonite containing synplutonic mafic pods, a middle unit of granite, and an upper roof unit of
406 quartz monzonite. The lower and middle units are considered to represent the segregated melt-
407 rich and crystal-rich portions, respectively, of a solidifying magma body; the upper unit is
408 thought to represent a solidification front. Synplutonic mafic pods have been interpreted as
409 indicating injections of variably contaminated mantle-derived magma in the source region.

410 Several large volcanic–plutonic complexes have been described from the Mesozoic
411 Yanshanian magmatic belt of southeastern China, mainly in western Guangdong [*Geng et al.*,
412 2006], Fujian [*Qiu et al.*, 1999] and Jiangxi [*Yang et al.*, 2011] provinces. However, most of
413 these studies have focused on petrological and geochemical aspects, and relatively few details
414 are readily available on pluton-caldera dimensions, subvolcanic structural connections, and
415 volumes of erupted materials. Nevertheless, the increasing application of high precision U-Pb
416 zircon geochronology to studies of such complexes has revealed the potential for close analogies
417 with Hong Kong. For example, the Early Cretaceous Xiangshan volcanic–plutonic complex in
418 Jiangxi Province [*Yang et al.*, 2011] comprises an early stage of fissure-fed dacite to rhyolitic
419 welded ignimbrite eruption, with associated monzogranite porphyry, and a late stage, central
420 vent caldera-forming eruption of rhyolite tuff, with associated injection of quartz monzonite and
421 high-K mafic dikes. Interestingly, the U-Pb zircon ages reveal that the emplacement of the
422 Xiangshan magmatic complex took place over approximately two million years, which is of
423 similar duration to the Early Cretaceous ‘flare-ups’ in Hong Kong.

424 **7. Conclusion**

425 The exceptional detail afforded by this remarkable crustal section through a nested
426 caldera complex in southeastern Hong Kong provides a direct window into the magmatic and
427 tectonic origins of large, overlapping, silicic magmatic systems. Reconstruction of the geometry
428 of the nested caldera complex, based on meticulous field observations, high precision
429 geochronology, whole-rock geochemistry, and geophysical surveys, reveals that the 143 Ma
430 volcanic–plutonic assemblage was extensively dismembered by development of the spatially
431 overlapping 141 Ma High Island Caldera. Rapid evacuation of a large, shallow, silicic magma
432 chamber during the 141 Ma ‘flare-up’ possibly induced asymmetric collapse of the nested

433 caldera complex to produce a local NE-oriented tilted crustal section. Volcanic conduits from
434 which immense 141 Ma eruptions took place were concentrated mainly along caldera ring fault
435 zones, some of which permitted the collapse of kilometer-scale crustal blocks to abyssal depths
436 of the underlying magma chamber. These are now preserved either as composite (quartz
437 monzonite to monzogranite) feeder dike complexes, or as quartz monzonite and monzogranite
438 stocks. The volcanic conduits, and the structures within which they occur, therefore reveal a
439 direct connection between the magma chamber and the extrusive rocks. They were exploited
440 repeatedly during the 141 Ma ‘flare-up’, from the early stage extrusion of trachydacite to rhyolite
441 lavas and tuffs, through the main stage eruption of the High Island tuff, to the late extrusion of
442 less differentiated magma. The rapid accumulation, ponding, and uniform cooling of the
443 intracaldera High Island tuff resulted in the development of the spectacular columnar-jointed
444 rhyolitic rock masses. Many of the features of the tilted nested caldera complex warrant further
445 examination, the details of which are beyond the scope of this paper. However, it is hoped that
446 future studies will provide valuable new insights into magma assemblies, eruption mechanisms,
447 and structural development of large silicic magmatic systems.

448 The nested caldera complex in southeastern Hong Kong is considered to represent an
449 exemplar of similar Middle Jurassic to Early Cretaceous magmatic systems that were replicated
450 many times during ignimbrite ‘flare-ups’ over 100,000’s of square kilometers along the
451 southeastern seaboard of China. We consider that the Early Yanshanian magmatic belt in
452 southeastern China culminated in a surge of pulsed supereruption scale magmatic activities
453 straddling the Jurassic–Cretaceous boundary and ended abruptly at approximately 141 Ma. The
454 ignimbrite ‘flare-ups’ recognized in Hong Kong represent a microcosm of these activities. Such
455 voluminous ignimbrite ‘flare-ups’ coinciding with the end of the Early Yanshanian magmatic

456 period would have had global environmental impact and may have influenced the widespread
457 extinction event among marine tetrapod and terrestrial dinosaur faunas at the end-Jurassic
458 [Bakker, 1978; Barrett *et al.*, 2009; Benson *et al.*, 2009].

609 **FIGURE CAPTIONS**

610 Figure 1. Distribution of Middle Jurassic–Early Cretaceous volcanic–plutonic associations and
611 location of key tectonomagmatic elements in Hong Kong (after Campbell and Sewell, 1997).

612 Figure 2. Geology of southeastern Hong Kong. HIT – High Island tuff, RHY – Rhyolite lava, T-
613 VT – Trachytic subgroup - welded fine ash Vitric Tuff, T-CVT – Trachytic subgroup - Crystal-
614 bearing fine ash Vitric Tuff, R-CAT-D – Rhyolitic subgroup - Dacitic Coarse Ash crystal Tuff,
615 R-CAT-R – Rhyolitic subgroup - Rhyolitic Coarse Ash crystal Tuff, G – Granite, M – Quartz
616 Monzonite (see also Figure 4).

617 Figure 3. A: TiO₂ versus Zr plot for the 143 Ma volcanic assemblages. T-VT – Trachytic subgroup
618 - welded fine ash Vitric Tuff, T-CVT – Trachytic subgroup - Crystal-bearing fine ash Vitric Tuff,
619 R-CAT – Rhyolitic subgroup. B: TiO₂ versus Zr plot for the 141 Ma volcanic assemblages. HIT –
620 High Island tuff, RHY – Rhyolite lava. (Geochemical data used for plots are listed in data sets
621 DS01 and DS02)¹.

622 Figure 4. Composite stratigraphic column for Early Cretaceous nested volcanic centers.

623 Figure 5. Illustrations of field and rock characteristics. A) Thin section photomicrograph of densely
624 welded, High Island tuff [after *Strange et al.*, 1990], B) Columnar-jointed welded High Island tuff
625 exposed on North Ninepin Island, eastern New Territories, C) Base of the High Island tuff resting
626 on tuff breccia, South Ninepin Island, eastern New Territories, D) Polymictic tuff breccia
627 representing volcanic conduit material exposed at Sai Kung, eastern New Territories, E) Coeval
628 mafic enclave displaying typical cusped terminations in 141 Ma granite, northern Lamma Island,
629 F) Mafic dike injected along kink-band in columnar-jointed High Island tuff at High Island
630 Reservoir Dam, eastern New Territories. .

631 Figure 6. Selected Harker diagrams to illustrate comagmatic relationships between plutonic rocks
632 (quartz monzonites and monzogranites) and volcanic rocks for the 141 Ma ‘flare-up’. RHY –

¹ Auxiliary Materials are available at <ftp://ftp.agu.org/apend/gc/2011gc003865>

633 Rhyolite lava; HIT – High Island tuff; GT/MZ – Granite/Monzonite dikes. (Geochemical data used
634 for plots are listed in data set DS03).

635 Figure 7. A: Combined offshore magnetic map, Euler gravity anomalies, major faults and magnetic
636 lineaments (after Fletcher et al., 1997; Sewell et al., 2000). B: Geologic map of the tilted nested
637 caldera-complex showing locations of key stratigraphic units, major faults and tectonomagmatic
638 boundary elements (see Figure 2 for key to abbreviations).

639 Figure 8. Block diagrams illustrating structural evolution of the tilted Early Cretaceous nested
640 caldera complex in southeastern Hong Kong (T – Trachytic subgroup, R – Rhyolitic subgroup, see
641 Figure 2 for key to other abbreviations). A: Shortly after High Island tuff eruption. B: Subsequent
642 crustal tilting by ~30 degrees. C: Uplift and erosion to reveal present-day section.

Table 1. Summary of Middle Jurassic to Early Cretaceous Volcanic–Plutonic Associations in Hong Kong [after *Sewell et al.*, 2000].

Magmatic Episode	Volcanic Group		Granitic Suite		Age ^a (Ma)
	Name	Main distribution	Name	Main distribution	
1	Tsuen Wan Volcanic Group (TWVG)	NE and NW New Territories	Lamma Suite (LS) - A-type Subsuite - I-type Subsuite	Central and W New Territories, Lamma and Lantau	165-160
2	Lantau Volcanic Group (LVG)	Central and W Lantau	Kwai Chung Suite (KCS)	E Lantau and S New Territories	148-146
3	Repulse Bay Volcanic Group (RBVG) - Rhyolitic Subgroup (R) - Trachytic Subgroup (T)	S Hong Kong, N Kowloon and Sai Kung	Cheung Chau Suite (CCS)	W Lantau and S New Territories	143
4	Kau Sai Chau Volcanic Group (KSCVG)	E New Territories	Lion Rock Suite (LRS) - Granite Subsuite (G) - Quartz Monzonite Subsuite (M)	N Hong Kong, Kowloon and E Lamma	141

^aBased on high precision U-Pb zircon ages [*Davis et al.*, 1997; *Campbell et al.*, 2007; *Sewell et al.*, 2012].

Table 2. General Petrologic Characteristics of Early Cretaceous Volcanic and Plutonic Rocks of Hong Kong [after *Sewell et al.*, 2000].

	Repulse Bay Volcanic Group (143 Ma)		Kau Sai Chau Volcanic Group (141 Ma)		
	Rhyolitic Subgroup	Trachytic Subgroup	Clear Water Bay 'lavas and tuffs'	High Island tuff	
Colour	Light grey to pinkish grey	Pale grey to bluish grey	Bluish grey to black	Pinkish grey	
Texture	Coarse ash crystal tuff	Crystal-bearing fine ash vitric tuff	Porphyritic lava and fine ash vitric tuff	Crystal-bearing fine ash vitric tuff	
Composition	Dacite to rhyolite (66–75 wt% SiO ₂)	Trachydacite to high-silica rhyolite (63–77 wt% SiO ₂)	Trachydacite to high-silica rhyolite (64–77 wt% SiO ₂)	High-silica rhyolite (>75 wt% SiO ₂)	
Phenocrysts	Albite, oligoclase, microperthite, quartz, biotite (c.50%)	Quartz, oligoclase, albite, microperthite (c.20%)	Albite, sanidine, microperthite, orthoclase, quartz (<8%)	Quartz, oligoclase, orthoclase, perthite, sanidine and biotite (c.20%)	
Lithics	Lava, tuff and rare granite	Rare	Rare	Rare	
Glass / pumice	Rare	Common	Common	Rare	
Fabric	Massive to crudely bedded	Non-welded to welded	Flow-banded and densely welded	Non-welded to densely welded	
		Cheung Chau Suite (143 Ma)		Lion Rock Suite (141 Ma)	
				Granite Subsuite	Quartz Monzonite Subsuite
Colour	Light grey or pink		Pale pink or grey		Light pinkish white to greyish white
Rock type	Biotite monzogranite		Biotite monzogranite		Quartz monzonite
Texture	Porphyritic medium-grained		Equigranular medium-grained to fine-grained		Porphyritic medium-grained
Feldspars	Zoned oligoclase, perthitic orthoclase		Microperthite, albite, zoned oligoclase,		Orthoclase, albite
Mafic minerals	Biotite		Biotite		Hornblende, biotite
Accessory minerals	Zircon, apatite, Fe-oxide, ± titanite, ± allanite		Zircon, Fe-oxide, ± apatite, ± titanite, ± allanite		Zircon, allanite, apatite, Fe-oxide, ± titanite
