

1 Presence and consequences of co-existing methane gas with
2 hydrate under two phase water-hydrate stability conditions

13

14 **KEY POINTS**

15 We present a method to calculate continuously saturations of pore phases during hydrate
16 formation/dissociation from pressure and temperature.

17 In our experiment up to 26% hydrate co-existed with about 12% gas in three hydrate formation
18 cycles with 10 and 55 MPa differential pressure

19 We suggest the dominant mechanism for gas and hydrate co-existence in our experiment is
20 formation of hydrate-enveloped gas bubbles.

21

22 **ABSTRACT**

23 Methane hydrate saturation estimates from remote geophysical data and borehole logs are needed

24 to assess the role of hydrates in climate change, continental slope stability, and energy resource

25 potential. Here, we present laboratory hydrate formation/dissociation experiments in which we

26 determined the methane hydrate content independently from pore pressure and temperature, and

27 from electrical resistivity. Using these laboratory experiments, we demonstrate that hydrate

28 formation does not take up all the methane gas or water even if the system is under two phase

29 water-hydrate stability conditions and gas is well distributed in the sample. The experiment

30 started with methane gas and water saturations of 16.5% and 83.5% respectively; during the

31 experiment, hydrate saturation proceeded up to 26% along with 12% gas and 62% water

32 remaining in the system. The co-existence of hydrate and gas is one possible explanation for

33 discrepancies between estimates of hydrate saturation from electrical and acoustic methods. We

34 suggest that an important mechanism for this co-existence is the formation of a hydrate film

35 enveloping methane gas bubbles, trapping the remaining gas inside.

36

37 **1 INTRODUCTION**

38 Hydrate is a naturally occurring ice-like, crystalline solid comprising a hydrogen-bonded
39 water lattice with trapped gas molecules, that forms in seafloor sediments at high pressures and
40 low temperatures (Kvenvolden, 1993). Nearly all the gas in natural hydrates is methane, with the
41 remainder comprising higher order hydrocarbons such as ethane (Kvenvolden, 1993). Remote
42 geophysical methods are used to quantify seafloor methane hydrates over broad areas. Typically
43 these methods exploit the increase in seismic velocity (e.g., Fohrmann & Pecher, 2012; Lee &
44 Collett, 2006b; Schnurle et al., 2004) and electrical resistivity (e.g., Hsu et al., 2014;
45 Schwalenberg et al., 2010; Weitemeyer et al., 2006) caused when hydrate replaces saline water
46 in sediment pores. However, accurate quantification of methane hydrate saturation is hampered
47 by uncertainties in the relationship between these parameters and hydrate content (e.g., Goswami
48 et al., 2015; Hsu et al., 2014; Lee & Collett, 2008; Schnurle et al., 2004).

49 Sub-seabed electrical resistivity can be measured using borehole logging (e.g., Miyakawa
50 et al., 2014) or marine controlled source electromagnetic (CSEM) methods (e.g., Weitemeyer et
51 al., 2006). Some field locations show discrepancies between hydrate saturations derived from
52 resistivity and seismic/sonic methods (Table 1). This difference is a potential source of
53 uncertainty in estimates from geophysical data of the carbon inventory stored in hydrate and in
54 resulting assessments of well stability and methane production from hydrate reservoirs.

55 Hydrate content is often estimated from the increase in electrical resistivity compared to
56 background sediments with no hydrates (e.g., Weitemeyer et al., 2006; Lee and Collett, 2008;
57 Schwalenberg et al., 2010; Hsu et al., 2014). However, this method does not differentiate
58 between gas and hydrate because both have higher resistivity than conductive pore fluid (e.g.,
59 Lee and Collett, 2008). Hereafter, the term gas is used to describe methane that is not stored in

60 hydrate or dissolved in water, and may be mobile or immobile. In seismic data, gas and hydrate
61 have been identified from a decrease and increase in P-wave velocity, respectively (e.g., Guerin
62 et al., 1999; Schnurle et al., 2004; Lee and Collett, 2006; Fohrmann and Pecher, 2012). Because
63 of their strong effect on P wave velocity (White, 1977), the presence of even small amounts of
64 gas can obscure any increase in velocity caused by the presence of hydrate. In this case, estimates
65 of hydrate content based on P wave velocity may differ significantly from those based on
66 resistivity.

67 The presence of co-existing hydrate and gas within the gas hydrate stability zone (GHSZ)
68 has been inferred in several locations away from seabed methane plumes (e.g., Guerin et al.,
69 1999; Milkov et al., 2004; Lee and Collett, 2006; Miyakawa et al., 2014). Such field studies have
70 attributed this presence of gas within the GHSZ to: (i) influx of gas into the GHSZ along
71 fracture/faults (Gorman et al., 2002; Lee & Collett, 2006b; Smith et al., 2014); (ii) local
72 deviations from two phase water-hydrate stability conditions (pressure-temperature-salinity)
73 resulting in local hydrate dissociation within the GHSZ (Guerin et al., 1999; Milkov et al., 2004);
74 or (iii) hydrate formation kinetics (Torres et al., 2004). Drilling activities may also dissociate
75 hydrates around a well, releasing gas within the GHSZ (Lee & Collett, 2006b).

76 At Site 1245 of ODP Leg 204, the amount of gas within the GHSZ was inferred
77 independently from NMR logs and sonic velocity logs, with four times less gas inferred from
78 sonic logs than from NMR logs (Lee & Collett, 2006b). In the Kumano basin, Nankai Trough,
79 offshore Japan, the presence of co-existing gas within the GHSZ was inferred from velocity and
80 resistivity logs: in certain parts of the well, velocity decreased with no corresponding decrease in
81 resistivity, probably due to the presence of gas (Miyakawa et al., 2014). In both these locations,
82 transport of gas into the GHSZ along faults or local hydrate dissociation during drilling has been

83 inferred (Lee & Collett, 2006b; Miyakawa et al., 2014). Milkov et al. (2004) explained the
84 presence of gas within the GHSZ at Site 1249 of ODP Leg 204 by high residual pore water
85 salinity, that limited further hydrate formation (Hesse & Harrison, 1981; Liu & Flemings, 2006;
86 Milkov et al., 2004). At Site 995 of ODP Leg 164, co-existing gas and hydrate in the base of the
87 GHSZ have been explained by hydrate dissociation in smaller pores because of capillary effects
88 along with hydrate stability in bigger pores (Guerin et al., 1999). Elsewhere, several locations do
89 not show any evidence of co-existing hydrate and gas within the GHSZ (e.g., Fujii et al., 2015).

90 However, gas can also be present in two phase water-hydrate stability conditions due to
91 two mechanisms. Firstly, hydrate can contain inclusions of gas (Schicks et al., 2006), which
92 could either be connected or disconnected to the pore network. Disconnected inclusions
93 (occlusions) could remain in the hydrate or could also be a pre-hydrate phase, where hydrate
94 formation is still in process (Schicks et al., 2006). Occlusions of gas may be removed over time
95 by diffusion, but in a dynamic pore fluid system with gas production, diffusion is unlikely to
96 dominate due to its relatively slow rate (Milkov et al., 2004; Suess et al., 2001). Secondly,
97 hydrate formation can block contacts between gas and water within sediment pores, and form
98 pockets of gas (which could include several pores) (e.g. Chaouachi et al., 2015; Yang et al.,
99 2016). Kinetic modelling of hydrate formation and dissociation in porous media suggests that it
100 is highly unlikely that hydrate can achieve true equilibrium because there are too many phases in
101 the system (e.g., Vafaei et al., 2014). Therefore, the limiting phase (methane in excess water
102 conditions; water in excess gas conditions) is unlikely to be completely used up to form hydrates
103 even if two phase water-hydrate stability conditions prevail.

104 Here, we present results from a laboratory experiment of methane hydrate formation and
105 dissociation in Berea sandstone. We calculated continuously the evolution of the brine, gas and

106 hydrate saturations during hydrate formation and dissociation from pore pressure and
107 temperature. Our calculation method does not assume that hydrate formation continues until the
108 limiting phase is exhausted, and we show that about 12% gas co-exists with 26% hydrate under
109 pressure, temperature and salinity conditions favorable for more hydrate formation.

110

111 **2 HYDRATE FORMATION AND DISSOCIATION EXPERIMENTS**

112 We conducted laboratory experiments involving repeated cycles of methane hydrate
113 formation and dissociation inside a high-pressure cell under excess water conditions.

114

115 **2.1 Sample properties and experimental setup**

116 For the test, we selected a 2 cm height, 5 cm diameter core sample of Berea sandstone.
117 The porosity was 0.22 and the absolute permeability was 448 mD ($\sim 4.5 \times 10^{-13} \text{ m}^2$) at
118 atmospheric conditions. The permeability was measured with (gas) permeameter and the porosity
119 with a pycnometer.

120 The experiment was conducted in a stainless steel triaxial cell core holder, designed to
121 host and pressurize 5 cm diameter rock samples up to 65 MPa of confining and pore pressure
122 (Figure 1), and instrumented to monitor temperature (both sample and ambient) (M. H. Ellis,
123 2008). The inner sleeve that prevents the direct contact between the mineral oil used as confining
124 fluid and the rock sample is perforated by 16 electrodes coupled to a data acquisition system.
125 Under typical operating conditions the relative error in resistivity measurement is $< 0.1\%$ (at
126 frequencies 1 - 500 Hz) for homogenous and isotropic samples in the electrical resistivity range
127 1-100 $\Omega \text{ m}$ (North et al., 2013). Axially, perspex buffer rods electrically isolate the sample from
128 the cell. The inner temperature sensor was placed on the outer side-wall of the sleeve at the

129 sample height, to provide accurate monitoring of the sample temperature. The pore fluid pipe
130 line is connected to (i) a pumping-syringe containing a 35 g/L NaCl solution in deionized-
131 deaerated water, (ii) a vacuum pump and (iii) a CH₄-bottle pressurized at 12 MPa (see Figure 1).

132

133 **2.2 Method of hydrate formation**

134 We followed the method of Waite et al. (2004) with an initial brine saturation of 83.5%
135 which allowed an excess water condition (M. H. Ellis, 2008; Priest et al., 2009). Our hydrate
136 formation method and experimental set up represent gas hydrate systems where localized gas
137 reaches the base of the GHSZ.

138 The sample was firstly oven-dried at 60°C, placed in the high pressure triaxial cell
139 (Figure 1), then a hydrostatic confining pressure of 10 MPa was applied externally to the sample.
140 A vacuum up to 1 Pa was applied internally to the sample to remove air from the pore space. The
141 presence of air affects the saturation calculation and also some gases present in the air, such as
142 CO₂, can form hydrate. A volume of brine (comprising 35 g/L NaCl solution in deionized and
143 deaerated water) was injected through the pore fluid line into the Berea rock sample using a
144 syringe pump, calculated to fill 83.5% of the pore space. Hence, the sample was only partially
145 filled with brine, with the remaining pore space available for subsequent methane gas injection
146 (e.g., Waite et al., 2004; Winters et al., 2004). We left the sample for three days so that the pore
147 fluids could re-distribute throughout the sample by capillary forces. The remaining pore space
148 (16.5%), which was previously under vacuum, may have been occupied by water vapor and/or
149 remaining air.

150 Methane gas was then injected to achieve a pore fluid pressure of 11.9 MPa (Figure 2),
151 and, simultaneously, the confining pressure was increased to 21.9 MPa to maintain a constant

152 differential pressure of 10 MPa during the whole experiment. The pore fluid system was sealed,
153 keeping the reservoir between the sample and valve V_A (Figure 1) filled with methane gas, which
154 is free to move in and out of the sample as a result of potential pore pressure variations. Finally,
155 four cycles of hydrate formation/dissociation were triggered by cooling/heating the setup in a
156 controlled manner, i.e., in and out from the gas hydrate stability conditions (GHSC).

157 The cooling of the system into the GHSC, to a set temperature of 5°C , generated a reduction
158 in pore pressure (Figure 2) that can be explained mainly by hydrate formation, with some
159 contribution from methane gas contraction and increased gas solubility. The pressure reduction
160 appears to take place in two stages (Figure 2). On trajectory A-B the system is cooled rapidly (in
161 5.5 hours). Here, the pressure drops due both to cooling and to hydrate formation. On trajectory
162 B-C the temperature remains around 5°C and only the pressure drops. Here, the pressure drop is
163 mainly due to hydrate formation and takes much longer (73 hours) than on trajectory A-B. The
164 formation of hydrate also generates a slight increase in temperature caused by exothermic hydrate
165 formation (Hwang et al., 1990). This increase is very clear on trajectory B-C. On trajectory A-B,
166 at around 201.4 h, there is a sudden pore fluid pressure and temperature increase (Figure 2). This
167 pressure increase is likely due to the interplay between the cooling of the system and the
168 exothermic effect of hydrate formation. Cooling and the consumption of pore fluids due to hydrate
169 formation both lead to a decrease in pressure. However, hydrate formation also leads to an increase
170 in temperature, which can result in a slight increase in pressure (Figure 2c and d). The net effect
171 depends on the balance between the rate of cooling and the rate of hydrate formation. Once hydrate
172 formation ceased, indicated by the end of the pore pressure decrease (point C in Figure 2), the
173 system was left at that pressure and temperature for several hours to ensure maximum hydrate

174 formation, evidenced by the horizontal asymptotic behavior of the pore pressure (Figure 2b) and
175 of the saturation lines for each cycle (Figure 3).

176 Hydrate dissociation was initiated by increasing the temperature above the GHSC to room
177 temperature. We also did a separate experiment under identical conditions in which we left the
178 sample under hydrate stability conditions at 5°C (point C in Figure 2a) for 1 month and saw that
179 maximum saturation of methane hydrate occurred in the first 75 hours. This experiment also
180 resulted in 22% hydrate saturation. The differential pressure was held at 10 MPa in the first and
181 second cycles of hydrate formation and dissociation, and then increased to 55 MPa for the third
182 and fourth cycles. This was done to explore the effects of micro-cracks on acoustic properties
183 (included in future work) that are generally open at lower differential pressures (10 MPa) and
184 closed at higher pressures (55MPa), based on previous resistivity and ultrasound data for Berea
185 (Han et al., 2011). The initial pore fluid pressure for the third cycle was 11.98 MPa (0.08 MPa
186 above that for the first cycle).

187 **3 SATURATION CALCULATIONS**

188 We tracked the evolution of the saturations of gas, brine and hydrate from the changes in
189 pore fluid pressure and temperature using the real gas equation (the PT method), and
190 independently from electrical resistivity measurements (the ERT method).

191 **3.1 PT method**

192 We calculated continuously the saturations of the three phases (gas, brine, hydrate) from
193 the changes in pore fluid pressure and temperature using the real gas equation. These
194 measurements were recorded at one minute intervals during the experiment. This method does
195 not assume that hydrate formation continues until the limiting phase is exhausted (e.g., Sultaniya

196 et al., 2015) nor that coexistence occurs only under three-phase stability conditions (e.g., You et
197 al., 2015). This allows us to deduce the physical processes that occur throughout the cycle of
198 hydrate formation and dissociation.

199 Our method assumes a closed system and conservation of the molar mass of methane and
200 water in the sample pore space. Methane can be present in hydrate, dissolved in brine or as gas.
201 Water can be present as liquid in the pore space (brine) or in hydrate (pure water). The pore
202 volume in the sample and inner volume of the input gas pipe were measured before starting the
203 experiment, and were assumed to remain constant throughout the experiment. A change in
204 effective pressure can change the sample's pore volume, but for the magnitude of the dynamic
205 stresses applied, this change is negligible (< 0.3% for Berea sandstone) (Rutter & Glover, 2012).
206 A change in temperature can also change the sample's pore volume. Such changes are likely to
207 be negligible in our experimental range (5 - 22 °C) as the volumetric thermal expansion
208 coefficient of sandstone is about 3×10^{-5} per °C in the temperature range 20 - 100 °C (Skinner,
209 1966). So we assumed the volume of the input gas pipe remains constant because it is always at
210 ambient pressure and the ambient temperature was controlled to 20 ± 2 °C. The pores of the
211 Berea sandstone can be occupied by gas, water or hydrate. Hydrate can only form in the pore
212 space of the sample and no hydrate forms in the gas input pipe because it is outside hydrate
213 stability conditions.

214 The non-ideal gas law is:

$$p V = n R T Z \quad (1)$$

215 where p is gas pressure, V is volume, n is the number of moles of methane gas, R is the
216 universal gas constant and T is temperature. Z is an empirical compressibility factor calculated
217 using the Peng–Robinson equation of state (Peng & Robinson, 1976), and varies with

218 temperature and pressure. Initially there was no hydrate in the sample. The sample pore volume
 219 V_{ts} was independently measured with a pycnometer, and a known volume of water V_{w0} ,
 220 measured using a syringe pump, was injected into the sample. The initial number of moles of
 221 water is given by

$$n_{w0} = \frac{V_{w0} D_{w0}}{M_w} \quad (2)$$

222 where D_{w0} is the density of brine at 35 g/L salinity and M_w is the molar mass of this brine. For
 223 the pipe, from eq. 1 we have

$$p_0 V_p = n_{p0} R T_{p0} Z_{p0} \quad (3)$$

224 where p_0 is initial gas pressure, which is the same in both the sample and the pipe, V_p is the
 225 volume inside the pipe, n_{p0} is the initial number of moles of methane gas in the pipe, T_{p0} is the
 226 temperature in the pipe, and Z_{p0} is the compressibility factor of methane under the initial pipe P-
 227 T conditions.

228 For the sample, eq. 1 gives

$$p_0 V_{ms0} = n_{s0} R T_{s0} Z_{s0} , \quad (4)$$

$$V_{ms0} = V_{ts} - V_{w0} , \quad (5)$$

229 where V_{ms0} is the initial volume of methane gas in the sample, n_{s0} is the initial number of moles
 230 of methane gas in the sample, T_{s0} is the initial temperature of the sample, and Z_{s0} is the
 231 compressibility factor of methane under the initial sample P-T conditions. In our method, we
 232 accounted for the dependency of methane solubility in water, denoted by b , on temperature and
 233 salinity (Tishchenko et al., 2005) and that of hydrate and brine densities on pressure and
 234 temperature (Lu & Sultan, 2008; Millero et al., 1980) using the equation:

$$n_{sw0} = V_{w0} D_{w0} b_0, \quad (6)$$

235 where n_{sw0} is the initial number of moles of methane in solution and b_0 is the initial solubility.

236 The total number of moles of methane in the system n_t was therefore

$$n_t = n_{p0} + n_{s0} + n_{sw0}. \quad (7)$$

237 Once the temperature decreases below that for hydrate stability, hydrate starts to form
 238 from the methane and water in the sample's pore space. This process reduces the sample's gas
 239 pressure, generating an inflow of methane gas from the pipe to regain equilibrium of pore fluid
 240 pressure. The net result is an overall decrease in the gas pressure. From this new gas pressure and
 241 the pipe and sample temperatures, T_p and T_s , we can calculate the number of methane moles in
 242 each phase. For a gas pressure p

$$V_h = n_h \frac{M_h}{D_h}, \quad (8)$$

$$V_w = (n_{w0} - n_h \cdot c) \frac{M_w}{D_w}, \quad (9)$$

$$V_{ms} = V_{ts} - V_w - V_h, \quad (10)$$

$$p V_p = n_p R T_p Z_p, \quad (11)$$

$$p V_{ms} = n_s R T_s Z_s, \quad (12)$$

$$n_{sw} = V_w D_w b, \quad (13)$$

243

244 where V_h is the volume of hydrate, n_h is the number of moles of hydrate, M_h is the molecular

245 mass of hydrate, D_h is the density of hydrate and c is the hydration number (i.e., the number of

246 water molecules required to form hydrate per molecule of methane). The total number of moles
 247 of methane in the system remains constant, so n_h can be obtained from

$$n_h = n_t - n_p - n_s - n_{sw}. \quad (14)$$

248 The hydrate saturation is given by

$$S_h = \frac{V_h}{V_{ts}}. \quad (15)$$

249 Combining equation 8-15, we obtain:

250

$$S_h \quad (16)$$

$$= \frac{\left(\frac{p_0 V_{p0}}{R T_{p0} Z_{p0}} + \frac{p_0 (V_{ts} - V_{w0})}{R T_{s0} Z_{s0}} + V_{w0} D_{w0} b_0 - \frac{p V_p}{R T_p Z_p} - \frac{p V_s}{R T_s Z_s} - V_w D_w b \right) \frac{M_h}{D_h}}{V_{ts}}.$$

251

252 All the symbols defined in this section are listed in Table 2 and constants are listed in Table 3.

253

254 3.2 ERT method

255 We estimated the saturation of resistive material in the pore space from measured bulk
 256 resistivity of the sample. As both hydrate and gas are resistive compared to the conductive brine,
 257 it is not possible to obtain the individual saturations of gas and hydrate separately by this approach.

258 To determine this saturation, the first step is to calculate the saturation of brine. Several
 259 approaches can be used to estimate the saturation of brine from measured electrical resistivity (e.g.,

260 Archie, 1942; Bussian, 1983; Glover, 2010; de Lima & Sharma, 1990; Revil et al., 1998;

261 Simandoux, 1963; Waxman & Smits, 1968). This interpretation is complicated in the presence of
 262 clay minerals as they have charge deficiency. The ‘counter ions’ required to balance this charge
 263 deficiency are in the double layer. These counter ions can move along the grain water surface
 264 under the influence of an external electric field. Hence, the macroscopic electrical conduction in a
 265 saturated/partially saturated porous medium with clay can be via a) bulk conduction caused by the
 266 movement of ions of the conducting pore fluid, and b) surface conduction in the vicinity of the
 267 fluid/grain interface (e.g. Bussian, 1983; Revil & Glover, 1998; Waxman & Smits, 1968). A wide
 268 variety of formulations have been developed to account for both surface and bulk conduction. The
 269 earlier models described the effect of surface conduction in terms of the volume of shale, while
 270 more recent models attempt to account for the physics of the diffuse ion double layer surrounding
 271 clay particles (e.g., Simandoux, 1963; Waxman and Smits, 1968; Clavier et al., 1984; Revil et al.,
 272 1998). We choose to use the Waxman-Smits formula for partial brine saturation (Waxman &
 273 Smits, 1968).

$$S_w = \left(\frac{\Phi^{-m} \rho_w}{\rho_t (1 + \rho_w B Q_v / S_w)} \right)^{\frac{1}{n}}, \quad (17)$$

$$B = 4.6 \left(1 - 0.6 e^{-\frac{1}{1.3 \rho_w}} \right), \quad (18)$$

$$Q_v = \frac{\text{CEC}(1 - \Phi) D_o}{\Phi}, \quad (19)$$

274
 275 where S_w is brine saturation, ρ_t is the measured sample resistivity, ρ_w is brine resistivity and Φ
 276 is porosity. Q_v is the concentration of clay exchange cations or counter ions per unit pore volume
 277 of the rock, and should be measured ideally in the laboratory by analyzing several samples with
 278 different brine saturations (Waxman & Smits, 1968). B represents the average mobility of the

279 counter ions near the grain surfaces, CEC is the cation exchange capacity, and D_o is mineral
280 grain density . The empirical parameters m and n are the cementation coefficient and the
281 saturation exponent, respectively.

282 Zhan et al., (2010) showed experimentally for a similar porosity Berea sandstone (22.98 -
283 23.60%) that the Waxman-Smits model gives reliable results for our salinity (Figure 6 of Zhan et
284 al., 2010). Glover et al. (1994) presented laboratory data on the variation of Berea sandstone
285 conductivity with fluid conductivity. They showed that, for low pore fluid conductivity (< 0.001
286 S/m), bulk conductivity is independent of pore fluid conductivity, and tends to be constant. For
287 higher pore fluid conductivity (< 1 S/m), the saturated rock conductivity is controlled mainly by
288 the movement of ions through the bulk fluid, and seems to be independent of any surface
289 conduction effect. As we used brine of 35 g/l (measured conductivity at 25 °C temperature is 5.2
290 S/m), we are in the higher pore fluid conductivity zone where surface conduction effects have
291 only a small effect on bulk rock conductivity. The experiments of Glover et al. (1994) and Zhan
292 et al. (2010) had no hydrate, but hydrate is resistive compared to saline pore fluid and has
293 negligible surface conduction (e.g., Lee & Collett, 2006a; Spangenberg, 2001). Several studies
294 have shown that surface conduction contributes substantially to the macroscopic conductivity at
295 low salinity and/or high temperature, even in low clay content sandstone (Bussian, 1983; Revil &
296 Glover, 1998; Waxman & Smits, 1968). Since our sample has a low clay content of 2.3% by
297 weight (XRD analysis; Han et al., 2015), the pore fluid has a high salinity (35gm/l NaCl with

298 conductivity of 5.22 S/m at 25 °C), and the temperature is low (5 °C), we conclude that the
299 Waxman-Smits model should be applicable in our case.

300

301 As natural hydrate can be found also in clay rich sediments, appropriate clay conduction
302 models should be used in such studies. We used the Waxman-Smits model but several
303 modifications, refinements, or other models exist. For example, Clavier et al. (1984) proposed
304 the dual water model, a modified form of the Waxman-Smits model with two types of pore
305 water, of which only one is affected by surface conduction. Kan and Sen (1987) modelled clays
306 as periodic arrays of charged insulating cylinders or spheres, immersed in symmetrical
307 monovalent electrolyte. Revil and Glover (1998) discussed the theoretical framework of surface
308 conduction predictions. Revil et al. (1998) accounted for the difference in behavior of anions and
309 cations. de Lima & Sharma (1990) discussed a model based on shape and occurrence of clay,
310 such as clay coating the sand grains or as individual clay grains. For a more detail review on
311 conductivity models refer to, for example, Doveton (2001); Glover (2010); de Lima & Sharma
312 (1990); Mavko et al. (1998).

313

314 The resistivity of brine is temperature-dependent and we calibrated it using the following
315 expression (e.g., McCleskey et al., 2012):

$$\rho_w = \frac{\rho_{25}}{1+\alpha(T-25)} , \quad (20)$$

316 where, T (°C) is temperature, α is the temperature compensation factor, and ρ_{25} (Ωm) is the
317 resistivity of brine at 25 °C. Values of ρ_{25} were measured using a conductivity meter with $\alpha =$

318 1.9%, similar to other studies (e.g. McCleskey et al., 2012). For a mixture of sand and clay, the
319 CEC can be calculated from

$$CEC = m_c \sum \chi_i CEC_i, \quad (21)$$

320

321 where, m_c is the mass fraction of clay minerals in the whole rock, χ_i is the relative volume fraction
322 of each clay mineral, and CEC_i is the cation exchange capacity of each clay mineral. The cation
323 exchange capacity of quartz can be neglected due to its large size (hence small amount of surface
324 change per unit mass) in comparison to clay minerals (D. V. Ellis & Singer, 2007).

325

326 This method of calculating CEC assumes a mixture of sand and clay, and does not account
327 for the various clay morphologies (e.g., clay as cement or grains) in Berea sandstone. We used
328 0.09 meq/g CEC for authigenic illite (Thomas, 1976). A value of 2 was used for n (Waxman &
329 Smits, 1968). The value of m was determined by fitting the initial resistivity for the known initial
330 brine saturation, found to be 2.825, which is within the range of 1.3 to 4 reported by Jackson et al.,
331 (1978). As hydrate forms, the value of m increases (Chen et al., 2008; Spangenberg, 2001), but
332 the exact form of this increase is not known. To account for this change, we arbitrarily assumed a
333 slightly higher value of $m = 3.1$ for hydrate saturations above 5% (Chen et al., 2008; Spangenberg,
334 2001). Spangenberg (2001) modelled the variation of n with water saturation, during hydrate
335 formation. He showed, n increases significantly only for water saturation below 40% and n is

336 almost constant for water saturation above 40%. In our experiment water saturation started from
337 83.5% and decreased up to 62% with hydrate formation; hence, we did not vary the value of n .

338

339 **4 RESULTS AND DISCUSSION**

340

341 **4.1 Three phase co-existence**

342 The results of the PT method provide evidence for the co-existence of methane gas,
343 methane hydrate and brine in our experiments. When the pressure and temperature reached
344 stability conditions, methane hydrate nucleation and growth started, followed by an increase in
345 hydrate saturation and a decrease in gas and brine saturation (Figure 3). Even though we allowed
346 enough time (80 - 180 h) for hydrate formation to continue (see Section 2 for further details), and
347 there was always stoichiometrically sufficient methane gas and brine available for more methane
348 hydrate formation, the reaction stabilized at a maximum methane hydrate saturation between 23-
349 26% and methane gas saturation between 12-13% of the pore space (Figure 3). The maximum
350 relative error in saturation calculated using the PT method is less than 0.5%. This phenomenon
351 was observed also in two additional cycles of methane hydrate formation and dissociation,
352 indicating the co-existence of three phases (gas, brine and hydrate) with similar maximum
353 methane hydrate and methane gas saturations, and an asymptotic behavior of the saturation
354 curves during hydrate formation in each cycle (Figure 3). At the maximum hydrate saturation,
355 application of small perturbations in the confining pressure could have ruptured hydrate shells,
356 trapping gas and allowed further hydrate formation (Fu et al., 2017). Such perturbations were not
357 applied, so our estimate of co-existing gas may represent an upper bound for our experimental
358 set up.

359 Methane hydrate is a non-stoichiometric solid with variable cage occupancy (Sloan &
360 Koh, 2007). We used a hydration number of 6.39, corresponding to 90% cage occupancy (Sloan
361 & Koh, 2007) for the calculation shown in Figure 3. If the cage occupancy is 100%, c is 5.75
362 (Sloan & Koh, 2007) and the resulting maximum hydrate saturation decreases by 2 %.

363 In Section 1, we listed several mechanisms allowing three phase coexistence of methane
364 gas with hydrate. Here, we discuss some of the mechanisms that are relevant to our experimental
365 study. Methane hydrate may form when methane gas and water are in contact and have
366 conditions favorable for hydrate formation. Our experimental pressure and temperature
367 conditions of 8.8 MPa and 5 °C were well within the hydrate stability field for 35 g/L brine, but
368 the salinity of the remaining pore water increases due to hydrate formation. Our experiments
369 started with 35 g/L salinity, and a 26% hydrate saturation would have increased the mean salinity
370 to about 46 g/L. At this salinity, our experimental pressure and temperature conditions are still
371 within the GHSC (Figure 2a), as calculated using the approach of Tohidi et al., (1995). This
372 calculation does not consider the effect of porous medium properties such as pore size, surface
373 structure and mineral composition that can all affect the GHSC (e.g. Handa and Stupin, 1992;
374 Clennell et al., 1999; Henry et al., 1999). Some experimental results suggest that surface
375 structure and mineral composition may have little effect on GHSC (Riestenberg et al., 2003),
376 while capillary effects due to pore size can be important (Clennell et al., 1999; Uchida et al.,
377 2004). Therefore, we consider only capillary effects.

378

379 Clennell et al., (1999) argued that methane hydrate behavior can be analogous to that of
380 ice, as also suggested by other authors (e.g. Handa and Stupin, 1992). The freezing point of ice is
381 lower in a fine-grained porous medium, such as soil, than in bigger pores, such as in sand. This is

382 due to curved water-ice interfaces that increase the free energy of pore water (Everett, 1961). In
 383 small pores, the curvature is high and the excess free energy is also high. In big pores, the
 384 curvature is low, and so is the excess free energy. Clennell et al. (1999) calculated the decrease
 385 in the freezing point of ice inside a pore relative to the bulk freezing point (in a pore of infinite
 386 pore radius), and extrapolated that to methane hydrate. We rearranged equation 8 of Clennell et
 387 al. (1999) to calculate the minimum pore radius for which hydrate can form under our
 388 experimental conditions of 8.8 MPa and 5 °C.

$$r_e = \frac{2\gamma_{iw}T_{i,bulk} \cos \theta_{iw}}{\rho_w \Delta H_{f,i} \Delta T_{i,pore}}, \quad (22)$$

389 where, r_e is the radius of the pores, γ_{iw} is the specific surface energy between ice and water,
 390 $T_{i,bulk}$ is the absolute melting temperature of ice (without considering pore radius effects), θ_{iw} is
 391 the wetting angle, ρ_w is the density of water, $\Delta H_{f,i}$ is the specific enthalpy of formation of ice
 392 and $\Delta T_{i,pore}$ is the change in melting temperature due to pore size effects. For our experimental
 393 pressure of 8.8 MPa, the hydrate-water phase boundary temperature ($T_{i,bulk}$) is 9.8 °C (calculated
 394 using the approach of Tohidi et al., 1995), and therefore $\Delta T_{i,pore}$ is -4.8 °C , giving a minimum
 395 pore radius of 9.5 nm for $\gamma_{iw} = 26.7 \text{ mJ m}^{-2}$, $\theta_{iw} = 180$ degrees, $\rho_w = 1000 \text{ kgm}^{-3}$, $\Delta H_{f,i} = 333$
 396 kJ Kg^{-1} (Clennell et al., 1999).

397
 398 We also measured the pore size distribution using X-ray computed tomography at the Swiss
 399 Light Source (SLS) at the Paul Scherrer Institute. The optical objective used for imaging was
 400 20x, which provided 325 nm voxel resolution. The pore size varied from 11.39 μm to 73.11 μm ,
 401 so capillary effects in our sample should not have limited the formation of hydrate. Note that
 402 only a small part (7.27 mm diameter and 8 mm high) of the sample was studied in the CT scan,

403 and we assumed that the observed pore size distribution is representative of the whole sample.
404 Clennell et al.'s (1999) equation is for pure water, while our pore fluid had an average salinity of
405 up to 46 g/L at maximum hydrate saturation. Sun and Duan (2007) developed a thermodynamic
406 model for the effect of pore size and salinity on hydrate stability. We used their open online
407 calculator (models.kl-edu.cn/models.htm) and found a minimum pore radius of less than 3.2
408 nm, confirming the minor effect of pore size for our experimental conditions. We note also that it
409 is very unlikely that hydrate formation can reduce the effective pore size to values close to the
410 minimum pore radius because that could only happen when the pore is almost completely
411 occupied by hydrate.

412

413 When hydrate forms, it can create a physical barrier between methane gas and water that
414 prevents further hydrate formation. This physical barrier can be of various types:

415 a) Hydrate may form and dissociate only near the inlet pipe if the methane gas/brine is
416 not distributed in the sample. This scenario is highly unlikely because the sample was vacuumed
417 and then 83% of the pore space was filled with brine. These conditions were kept for three days,
418 allowing the brine to spread within the sample. The gas would also be distributed within the
419 sample before hydrate forms because: (i) the inlet pipe is on the lower surface of the sample, and
420 methane gas would likely move upwards due to buoyancy; and (ii) methane gas was injected into
421 the sample at room temperature and left for three days to complete its upward migration before
422 cooling the system into the hydrate stability field.

423 b) Isolated pockets of gas or brine could exist in some pores. This can be due to gas
424 reaching a pore that is not connected in the flow direction, and/or capillary trapping. If such a
425 pore is blocked in the flow direction, hydrate formation can trap the gas (Figure 4, A). Similarly,

426 hydrate formation in connected pores could also disconnect them, trapping brine/gas (Figure 4,
427 B). Capillary trapping can occur when the gas pressure is less than the capillary entry pressure of
428 a given pore, which depends on its radius, resulting in the fluid being unable to move through
429 that pore (Figure 4, C). The formation of hydrate can enhance this trapping mechanism by
430 decreasing the effective pore radius, resulting in higher threshold capillary pressures needed for
431 gas invasion (Figure 4, D).

432 c) Unconnected pores (occlusions) of gas/water can occur within hydrates (Figure 4, E).
433 In our experiment, the maximum hydrate and gas saturations are around 26% and 12% of the
434 pore space, respectively. Near seafloor sediments on the southern summit of Hydrate Ridge
435 (offshore Oregon, USA) contain porous hydrates that likely formed when methane gas bubbles
436 became coated with a hydrate film as they moved upwards within the sediments and coalesced
437 together (Suess et al., 2001). A sufficiently thick hydrate film enveloping the methane bubbles
438 disconnects the gas remaining inside the hydrate film from the pore water outside (Figure 4, F).
439 Hence, gas remains trapped within the hydrate film, even though hydrate stability conditions
440 prevail. Such porous hydrates have 55 ± 5 % of their bulk volume filled with gas (Suess et al.,
441 2001). Similar porous hydrate has also been recovered offshore Nigeria, with pore diameter of 2-
442 3 mm (Sultan et al., 2014). We propose that this is the dominant mechanism for co-existing gas
443 in our experimental setup. This mechanism does not involve three phase thermodynamic
444 equilibrium, as the trapped methane gas inside the hydrate shell is not in physical contact with
445 water outside the shell.

446 During drilling in a pockmark offshore Nigeria, Sultan et al. (2014) observed a vigorous
447 flow of gas in the GHSZ, just after penetrating a thin hydrate layer at around 18 meters below
448 sea floor. These authors attributed this flow to rapid influx of gas along fractures in the GHSZ,

449 which leads to rapid hydrate formation, primarily along the inner surface of fractures, leading to
450 isolation of free gas from the surrounding pore fluid. This mechanism is similar to the one that
451 we propose, but at much larger scale.

452 Gas trapped within hydrate films would diffuse out over geological time scales, so our
453 experimental results might not reproduce well hydrate formation in nature. However, in a
454 dynamic natural system with ongoing gas flow into the GHSZ, methane bubbles with a hydrate
455 film enveloping them can also be present. Samples collected from the shallower sediments at
456 Hydrate Ridge show that the residence time of such hydrate enveloped-methane bubbles may be
457 less than the time needed for diffusion (Suess et al., 2001).

458 Further evidence for such gas trapping comes from a laboratory study of methane
459 production by hydrate dissociation by heating that showed an abrupt peak in methane production
460 rate, while the rate of water production remained almost constant (Tang et al., 2005), perhaps
461 due to release of co-existing methane gas. A similar abrupt peak in methane production has been
462 observed also using depressurization (Xiong et al., 2012).

463

464 **4.2 Effect of co-existing gas within the GHSZ on hydrate saturation estimates**

465 Resistivity based methods for determining hydrate saturation do not differentiate between
466 gas and hydrate; all resistive material in the pore space within the GHSZ is generally interpreted
467 as hydrate (e.g., Hsu et al., 2014; Schwalenberg et al., 2010; Weitemeyer et al., 2006). Similarly,
468 in our experiment, if we interpret all resistive material in the pore space as hydrate, the ERT
469 method over-estimates the hydrate saturation because both gas and hydrate are resistive
470 compared to brine (Figure 5). Small apparent fluctuations in the total amount of resistive
471 material inferred from ERT results come from uncertainty when selecting the empirical

472 parameters in equation 17 (Section 3.2). The PT method can differentiate between methane gas
473 and hydrate because gas and hydrate have different volumetric densities (Section 3.1). In our
474 laboratory experiment, up to 36% of the resistive material remained as gas. In a borehole
475 offshore Japan, the difference between hydrate saturation from resistivity methods and from
476 sonic methods was *c.* 50%, likely due to co-existing gas (Miyakawa et al., 2014). Table 1 lists
477 other field studies with differences in hydrate saturation inferred from resistivity methods and
478 seismic/sonic methods.

479 Further uncertainties in methane quantification based on resistivity data can occur due to
480 such co-existing gas. The methane content per unit volume of the gas phase is different to that of
481 the hydrate phase. The difference depends on the molar volumes of hydrate and gas, which in
482 turn depend on pressure and temperature, with greater variations in the gas phase than in the
483 hydrate phase. Hence, the uncertainty in the methane inventory is larger in shallower water
484 depths where gas molar volumes are higher. The methane content of the GHSZ is over-estimated
485 in shallower waters (e.g., less than *c.* 1250 m depth for the Arctic Ocean) and under-estimated in
486 deeper waters, where the molar volume of methane gas is less than that of hydrate. If the amount
487 of co-existing gas within the GHSZ is significant, then it can affect the estimate of carbon
488 content, and the geophysical and mechanical properties of the hydrate bearing sediments. Current
489 numerical models that simulate the behavior of natural and laboratory hydrate systems do not
490 account for this type of co-existing gas. Additional work is needed to support further our results,
491 such as performing a similar study on different types of samples, and/or synchrotron X-ray
492 computed tomography of hydrate- and gas-bearing samples.

493

494 **5 CONCLUSIONS**

495 In repeated cycles of hydrate formation and dissociation, our experimental results
496 demonstrate the co-existence of up to 26% hydrate with about 12% gas. We infer that not all of
497 the methane gas and water formed hydrate even when the two phase water-hydrate stability
498 conditions were satisfied. We suggest such co-existence occurs when methane gas bubbles
499 become enveloped in hydrate films. A sufficiently thick hydrate film would isolate the gas
500 trapped inside from the brine outside, even when hydrate stability conditions prevail. Such
501 methane bubbles enveloped in hydrate films have also been observed in samples from Hydrate
502 Ridge, offshore Oregon USA, with up to 55% of the bulk hydrate volume made up of co-existing
503 gas. Our experimental results show that hydrate formation from methane in the gas phase results
504 in up to 36% co-existing gas (as a percentage of the bulk hydrate volume).

505 Our results support the idea that co-existing gas may be present within the gas hydrate
506 stability zone in natural gas hydrate systems, with gas influx through fractures in fine-grained
507 sediments. We suggest that this co-existence of gas and hydrate is one possible explanation for
508 the differences in hydrate saturation estimates between resistivity and seismic/sonic observations
509 of natural hydrate systems.

510 **ACKNOWLEDGMENTS**

511 We acknowledge funding from the UK Natural Environment Research Council (grant no
512 NE/J020753/1). The data is available in the supplemental information and at the National
513 Geoscience Data Centre, UK (www.bgs.ac.uk/services/NGDC/home.html). Hydrate phase
514 boundaries were calculated by the Centre for Gas Hydrate Research at Heriot-Watt University
515 (<http://www.pet.hw.ac.uk/research/hydrate>), using the Heriot-Watt Hydrate and Phase
516 Behaviour Programme (HWHYD). We thank K. Amalokwu and E. Attias for their advice on
517 experimental troubleshooting. We thank P. J. Talling for his valuable comments on the
518 manuscript. T. A. Minshull was supported by a Royal Society Wolfson Research Merit award.
519 We also thank the editor Andre Revil, associate editor Ludmila Adam, reviewer Ingo Pecher and
520 two other anonymous reviewers for their valuable comments.

780

TABLE 2. PARAMETERS USED IN THE PT METHOD.

781

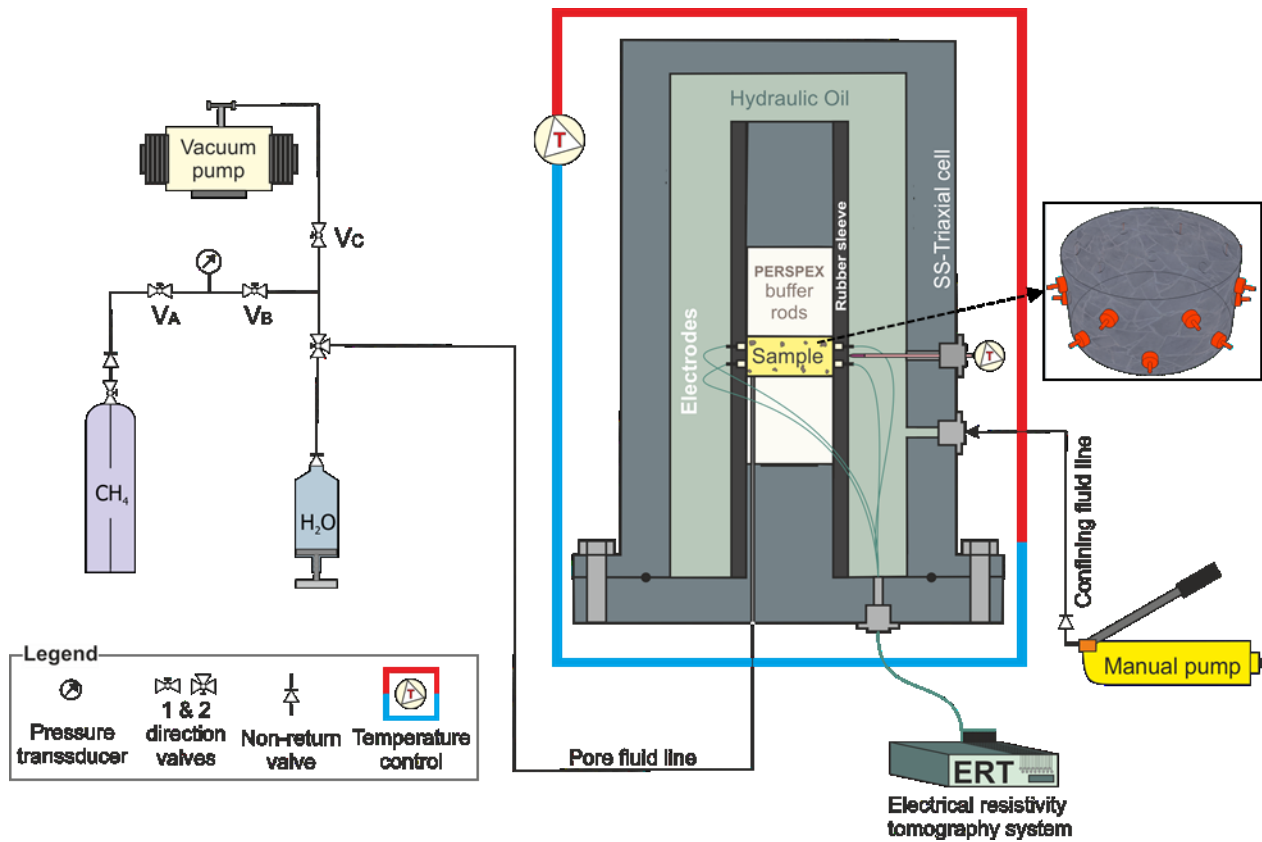

Description	Symbol*
Number of moles of methane hydrate	n_h
Saturation of methane hydrate	S_h
Pore fluid Pressure	p
Total pore space in the sample	V_{ts}
Volume of methane gas in the sample	V_{ms}
Volume of liquid water in the sample	V_w
Volume of hydrate in the sample	V_h
Volume of pipe	V_p
Total number of moles of methane in the system	n_t
Number of moles of methane gas in pipe	n_p
Number of moles of methane gas in sample	n_s
Number of moles of methane in solution	n_{sw}
Number of moles of water in liquid phase	n_w
Temperature in the pipe	T_p
Temperature in the sample	T_s
Compressibility of methane gas in the pipe	Z_p
Compressibility of methane gas in the sample	Z_s
Density of Brine	D_w
Density of Hydrate	D_h

782 *Initial values for these parameters are denoted in the text with a subscript 0

TABLE 3. CONSTANTS USE IN THE PT METHOD.

Description	Symbol	Values
Ratio of water to methane in hydrate (Sloan & Koh, 2007)	c	6.39
Molar mass of brine (35 g/L)	M_w	0.0186 Kg
Molar mass of hydrate (structure I)	M_h	0.1312 Kg
Universal gas constant	R	$8.314 \text{ Jmol}^{-1}\text{K}^{-1}$

785

786

787 Figure 1: Schematic diagram of the experimental setup, also showing the arrangement of
788 electrodes around the Berea rock sample (5 cm diameter). Scales are approximate.

789

Figure 2. Changes of a) pressure versus temperature, and b) pressure with time during methane hydrate formation and dissociation in Berea sandstone. Only the second cycle of hydrate formation and dissociation is shown for clarity. The green and black lines are the pure methane hydrate phase boundary for 35 g/L and 46 g/L salinity respectively, calculated using the approach of Tohidi et al. (1995). Blue dots represent cooling and red dots represent heating. In

a) time is shown in hours (h). Trajectory ABC marks cooling of the system to 5 °C and hydrate formation. Trajectory CD shows hydrate dissociation. c) and d) show pressure and temperature change with time during trajectory AB. See text for further details.

792

793 Figure 3. Evolution of water, methane gas and methane hydrate saturation during three hydrate
 794 formation and dissociation cycles in Berea sandstone. The saturations were calculated from the
 795 changes in pore pressure and temperature (Section 3.1). We used a hydration number of 6.39
 796 corresponding to 90% cage occupancy (Sloan & Koh, 2007). Note the contracted y-axis scale.
 797 The first cycle is not shown because the pressure logger malfunctioned. Relative error in
 798 saturation is less than 0.5%.

799

800 Figure 4. Conceptual model showing various mechanisms (marked A to F) for co-existence of
 801 methane gas and hydrate even when methane hydrate stability conditions prevail in the system.
 802 Red is methane gas, white is hydrate, brown is sand and blue is saline water (brine). A, B: pore
 803 blocked by hydrate formation. C: capillary pressure of pore not allowing the gas to move through
 804 it. D: capillary pressure of the pore increased by hydrate formation, not allowing further passage

805 of gas. E: occlusions (unconnected inclusions) of gas within hydrate. F: hydrate film enveloping
806 the gas bubble.

807

808

809 Figure 5. Total methane gas and methane hydrate saturations (volume percentage of pore space)
810 from the pressure temperature (PT) method plotted against saturation of all resistive material
811 deduced from the resistivity (ERT) method. Relative errors in the saturations calculated from the
812 ERT and PT methods are less than 2% and 0.5%, respectively.
