# Hydrological Summary for the United Kingdom 

#### Abstract

General Episodic weather patterns are a characteristic of the UK climate but the dramatic contrast between April and May rainfall totals has few close modern parallels．Following a very arid April，Britain registered its 2 nd wettest May for 72 years． Initially the parched soils limited the rainfall＇s effectiveness but appreciable reservoir replenishment occurred over the latter half of the month．Most reservoir stocks remained fairly static at a time when a modest decline is normally expected and，entering June，overall stocks for England \＆Wales were marginally above the early summer average．Stocks in most index reservoirs are within $5 \%$ of the early June average but overall stocks in Northern Ireland are moderately low．Contrary to the normal seasonal pattern，May runoff totals exceeded those for April in many areas and minor spate conditions were relatively common，around month－end especially．Notwithstanding record soil moisture conditions early in May，some modest but very useful infiltration was reported late in the month．Groundwater levels throughout the major aquifers are mostly within the normal range and set to follow recessions considerably above those which typified the last two summers． Correspondingly，no repetition of the degree of water resources and environmental stress experienced last year is anticipated through the summer of 2007.

## Rainfall

The high pressure，which was responsible for the remarkably dry and warm April，continued into May．After the first week however synoptic patterns changed decisively－allowing cyclonic conditions to become dominant across almost all of the country．The associated passage of a sequence of frontal systems produced two notably wet interludes．Storm totals exceeding 30 mm were common on the $13^{\text {th }}$ and，more exceptionally，a number of areas in the English Lowlands （e．g．parts of south Oxfordshire，Isle of Wight and Hertfordshire）registered 24－hr rainfall totals（ $27 / 28^{\text {th }}$ ）which exceeded the May average；Runley Wood，Luton reported 79.2 mm ．At Wallingford，the difference between the April and May rainfall totals was the $2^{\text {nd }}$ greatest for any monthly pairing in a series from 1962．A few areas（mostly in a zone from Northern Ireland to Northumbria）registered modestly below average May rainfall．By contrast，parts of northern Scotland were very wet and most catchments to the south－ east of a line from the Bristol Channel to the Humber estuary reported more than twice the average rainfall．In the Thames valley，rainfall across the Thame catchment exceeded the previous May maximum in a series from 1920．Regional variations in rainfall anomalies for the spring（March－May） are large：Yorkshire and Northern Ireland reported their driest spring since 1997 and 1984 respectively whilst，in Scotland， the Highland Region added a further wet spring to a notable cluster in the last 20 years．Regional rainfall accumulations over a longer timespan（ $6-15$ months）are generally above average，exceptionally so for much of Scotland．

## River flows

The protracted April recessions continued into early May when exceptionally low late－spring flows were registered over wide areas．On the $5^{\text {th }}$ ，the Ribble marginally eclipsed its lowest May daily flow in a record from 1960．More notably，estimated total outflow from Britain for the first week of May was the lowest in a 48 －year series．From the second week，flows recovered briskly in many western， central and northern catchments with widespread modest spate conditions in mid－month．More unusually，flows in many rivers across the English Lowlands increased steeply following the notable Bank Holiday rainfall．Bankfull flows were exceeded（modestly）in some responsive rivers（e．g． the Thame）and several Flood Warnings were operational around month－end；some locally severe urban flooding was also reported（e．g．in Luton）．May runoff totals generally
reflect the counterbalancing effect of the contrasting flows in early and late month－most were well within the normal range．There were some exceptions：May runoff was high across most of north－west Scotland and in parts of the South West but considerably below average in some sheltered eastern catchments．The Whiteadder registered it $2^{\text {nd }}$ lowest runoff in a $39-\mathrm{yr}$ series and，in Northern Ireland，the Annacloy reported its lowest May runoff since the 1984 drought．Spring runoff for index catchments was mostly within the normal range but the Lower Bann registered its lowest March－May runoff in a series from 1980．By contrast， the lagged response to the very wet winter is evident in groundwater－fed rivers across southern England－the Lambourn reported its $3^{\text {rd }}$ highest spring runoff since 1975. Correspondingly，the lowland stream network is much more extensive than in the early summer of 2006．In Scotland， exceptional n－month runoff accumulations continue to be registered．

## Groundwater

May rainfall patterns favoured the outcrop areas of the major aquifers－large parts of the Chalk registered around twice the monthly average．The exceptionally high soil moisture deficits over the early part of the month greatly limited the hydrological effectiveness of the rainfall but，as soils in many areas approached saturation towards month－end，infiltration was reported over many outcrop areas（estimated at over twice the May average in parts of the Chilterns）．This seasonally late pulse of recharge is particularly useful at a time when groundwater level recessions are normally well established．However，the modest recharge is not reflected in the generality of index borehole hydrographs－most reporting dates preceded the notably wet spell around month end．Modest increases in groundwater levels were registered in the responsive Oolitic Limestone of the Cotswolds （Ampney Crucis）and in the Lower Greensand at Frith Cottage（South Downs）．Elsewhere，and notwithstanding the very erratic recharge patterns in 2007，the May hydrographs mostly testify to a typical spring recession． However in Northern Ireland，well below average spring rainfall has seen levels at Killyglen decline to close to the May minimum．The legacy of drought conditions in 2004－ 06 is still evident in the slowest－responding parts of the Permo－Triassic sandstones aquifer but levels are continuing to rise－reaching their highest level for two years at Heathlanes．

## Rainfall accumulation map

Spring rainfall (March-May) for the UK as a whole was marginally above average but spatial variations were substantial. Rainfall totals were considerably below average in a broad zone from south-east Scotland to the north Midlands (and extending to Northern Ireland). Over the post-September 2006 period however, all regional rainfall anomalies are positive, notable so across most of Scotland and much of southern Britain.

## River flow . . . River flow

## River flows

*Comparisons based on percentage flows alone can be misleading. A given percentage flow can represent extreme drought conditions in permeable catchments where flow patterns are relatively stable but be well within the normal range in impermeable catchments where the natural variation in flows is much greater. Note: the period of record on which these percentages are based varies from station to station. Percentages may be omitted where flows are under review.

## River flow . . . River flow

## River flow hydrographs

The river flow hydrographs show the daily mean flows together with the maximum and minimum daily flows prior to June 2006 (shown by the shaded areas). Daily flows falling outside the maximum/minimum range are indicated where the bold trace enters the shaded areas.

## Groundwater . . . Groundwater

Groundwater levels normally rise and fall with the seasons, reaching a peak in the spring following replenishment through the winter (when evaporation losses are low and soil moist). They decline through the summer and early autumn. This seasonal variation is much reduced when the aquifer is confined below overlying impermeable strata. The monthly mean and the highest and lowest levels recorded for each month are displayed in a similar style to the river flow hydrographs. Note that most groundwater levels are not measured continuously - the latest recorded levels are listed overleaf.

## Groundwater levels - May 2007

The rankings are based on a comparison between the average level in the featured month (but often only single readings are available) and the average level in each corresponding month on record. They need to be interpreted with caution especially when groundwater levels are changing rapidly or when comparing wells with very different periods of record. Rankings may be omitted where they are considered misleading.
Notes: i. The outcrop areas are coloured according to British Geological Survey conventions.
ii. Yew Tree Farm levels are now received quarterly.
iii. Data for Nuttalls Farm are currently under review.

| () figures in parentheses relate to gross storage |  | - denotes reservoir | groups | +excludes Lough Neagh |  |  |  | *last occurrence |  |  |

Details of the individual reservoirs in each of the groupings listed above are available on request. The percentages given in the Average and Minimum storage columns relate to the 1988-2006 period except for West of Scotland and Northern Ireland where data commence in the mid-1990's. In some gravity-fed reservoirs (e.g. Clywedog) stocks are kept below capacity during the winter to provide scope for flood attenuation purposes.

# National Hydrological Monitoring Programme 

The National Hydrological Monitoring Programme (NHMP) was instigated in 1988 and is undertaken jointly by the Centre for Ecology and Hydrology Wallingford (formerly the Institute of Hydrology - IH) and the British Geological Survey (BGS). Financial support for the production of the monthly Hydrological Summaries is provided by the Department for Environment, Food and Rural Affairs (Defra), the Environment Agency (EA), the Scottish Environment Protection Agency (SEPA), the Rivers Agency (RA) in Northern Ireland, and the Office of Water Services (OFWAT).

## Data Sources

River flow and groundwater level data are provided by the Environment Agency, the Environment Agency Wales, the Scottish Environment Protection Agency and, for Northern Ireland, the Rivers Agency and the Department of the Environment (NI). In all cases the data are subject to revision following validation (flood and drought data in particular may be subject to significant revision).
Reservoir level information is provided by the Water Service Companies, the EA, Scottish Water and the Northern Ireland Water Service.

The National River Flow Archive (maintained by CEH Wallingford) and the National Groundwater Level Archive (maintained by BGS) provide the historical perspective within which to examine contemporary hydrological conditions.

## Rainfall

Most rainfall data are provided by the Met Office (see opposite). To allow better spatial differentiation the rainfall data for Britain are presented for the regional divisions of the precursor organisations of the EA and SEPA. Following the discontinuation of the Met Office's CARP system in July 1998, the areal rainfall figures have been derived using several procedures, including initial estimates based on MORECS*. Recent figures have been produced by the Met Office, National Climate Information Centre (NCIC), using a technique similar to CARP. A significant number of additional monthly raingauge totals are provided by the EA and SEPA to help derive the contemporary regional rainfalls. Revised monthly national and regional rainfall totals for the post-1960 period (together with revised 1961-90 averages) were made available by the Met Office in 2004; these have been adopted by the NHMP. As with all regional figures based on limited raingauge networks the monthly tables and accumulations (and the return periods associated with them) should be regarded as a guide only.

The monthly rainfall figures are provided by the Met Office (National Climate Information Centre) and are Crown Copyright and may not be passed on to, or published by, any unauthorised person or organisation.
*MORECS is the generic name for the Met Office services involving the routine calculation of evaporation and soil moisture throughout Great Britain.

[^0]:    Important note:Figures in the above table may be quoted provided that their source is acknowledged. See page 12. Where appropriate, specific reference must be made to the uncertainties associated with the return period estimates. Generally, the return period estimates are based on tables provided by the Met Office" but those for Northern Ireland are based on the estimates for north-west England. The estimates relate to the specified region and span of months only (RPs may be an order of magnitude less if n-month periods beginning in any month are considered), they reflect rainfall variability over the period 1911-70 only, and assume a stable climate. (For further details see Tabony, R. C., 1977, The variability of long duration rainfall over Great Britain, Scientific Paper No. 37). The timespans featured do not purport to represent the critical periods for any particular water resource management zone and, normally, for hydrological or water resources assessments of drought severity, river flows and groundwater levels provide a better guide than return periods based on rainfall totals. "In some cases ranking positions of accumulated rainfalls are also considered.
    All monthly rainfall totals since December 2006 are provisional.
