Abstract The Beebe Vent Field (BVF) is the world's deepest known hydrothermal system, at 4960 m below sea level. Located on the Mid-Cayman Spreading Centre, Caribbean, the BVF hosts high temperature (~401°C) "black smoker" vents that build Cu, Zn and Au-rich sulfide mounds and chimneys. The BVF is highly gold-rich, with Au values up to 93 ppm and an average Au:Ag ratio of 0.15. Gold precipitation is directly associated with diffuse flow through "beehive" chimneys. Significant mass-wasting of sulfide material at the BVF, accompanied by changes in metal content, results in metaliferous talus and sediment deposits. Situated on very thin (2–3 km thick) oceanic crust, at an ultraslow spreading centre, the hydrothermal system circulates fluids to a depth of ~1.8 km in a basement that is likely to include a mixture of both mafic and ultramafic lithologies. We suggest hydrothermal interaction with chalcophile-bearing sulfides in the mantle rocks, together with precipitation of Au in beehive chimney structures, has resulted in the formation of a Au-rich volcanogenic massive sulfide (VMS) deposit. With its spatial distribution of deposit materials and metal contents, the BVF represents a modern day analogue for basalt hosted, Au-rich VMS systems.

1. Introduction

Seafloor hydrothermal vent sites are widely recognized features of rifting and seafloor spreading in a variety of tectonic settings, including slow and ultra-slow spreading centres [Beaulieu *et al.*, 2013]. In 2010, two hydrothermal vent fields were discovered in the Cayman Trough related to the ultra-slow spreading Mid-Cayman Spreading Centre [Connelly *et al.*, 2012] after the discovery of hydrothermal plumes in the area [German *et al.*, 2010]. These are the Beebe Vent Field (BVF, Figure 1a), and a moderate temperature site on an oceanic core complex, the Von Damm Vent Field. The BVF lies ~3 km to the east of the main spreading axis, and is situated on the eastern flanks of an axial volcanic ridge (Figure 1b). At nearly 5000 m below sea level (mbsl), the BVF is the deepest known hydrothermal site in the world. It hosts two main areas of focused hydrothermal flow at temperatures up to 401°C, and has developed mounds and aprons of sulfide material. The remarkable discovery of hydrothermal venting on the world's deepest spreading centre opens new possibilities for studying hydrothermal circulation and metal mobility under conditions of extreme pressure and temperature. As the BVF fluids exit the seafloor at conditions comparable to the subsurface reaction zone of typical fast spreading vent sites [Von Damm *et al.*, 1985; Von Damm and Bischoff, 1987; Scott, 1997], they may offer a unique insight into processes operating deep beneath shallower sites.

Here we present results of detailed mapping, sampling, mineralogical and geochemical analyses that reveal the BVF is an auriferous Cu-Zn volcanogenic massive sulfide (VMS) deposit in the making. We show that as a result of the high temperature and low salinity of fluids venting at the BVF, the fluids remain supercritical even at the point of exit from the vent orifice. The resulting precipitated sulfides are unusually auriferous, with up to ~90 ppm gold, which is unprecedented for any active basalt-hosted system. Furthermore, the heterogeneity in gold concentration between focussed-flow chimneys and diffuse-flow beehive chimneys suggests that chimney morphology exerts a strong control on the gold content of seafloor massive sulfide deposits.

2. Methods

Discovered in 2010 [Connelly *et al.*, 2012], The *RRS James Cook* returned to the BVF in February 2013 on leg JC82 where it deployed the ROV *Isis* to depths of over 5000 m for high-resolution swath sonar and

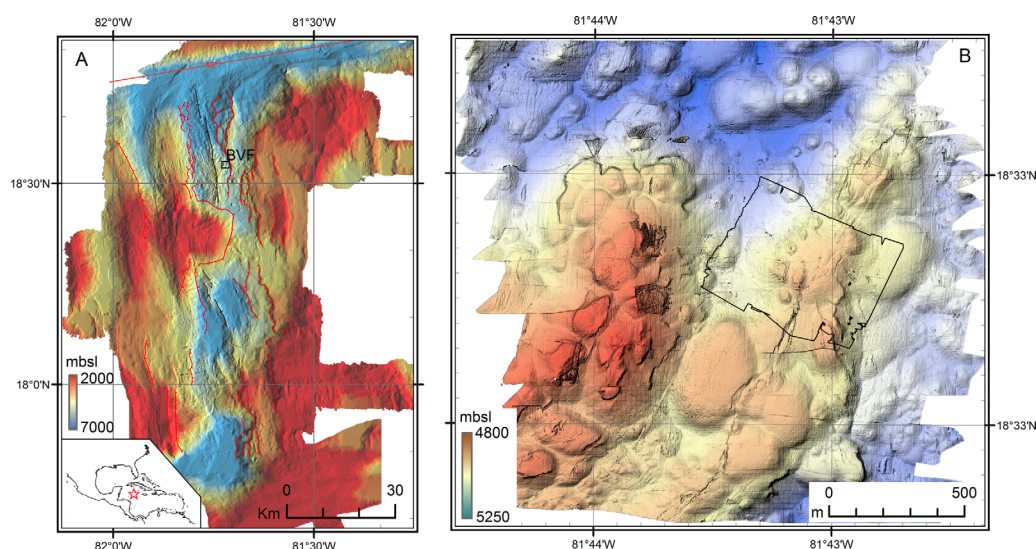

Figure 1. (a) Location of the Beebe Vent Field (BVF) in the Mid-Cayman Spreading Centre, Cayman Trough, and world location map (inset). Position of the BVF is given by the box, which shows the extent of (B). Major faults are displayed in red, located by processing the bathymetry for slope angle, and the spreading axis is shown in black. (b) The area immediately surrounding the BVF is composed of hummocky pillow basalt mounds. The BVF is situated on a NE-SW trending spur of lava domes. The mounds and metaliferous talus of the BVF can be seen on the western side of this spur, which is bisected by a fault network. The outline of the bathymetry shown in Figure 2 is given in black.

photographic mapping, and sampling of the vent fauna, fluids, sulfides and host rocks. The new swath map together with extensive exploration of the site during four dives, totaling over 90 h on the seafloor, allowed for a detailed geological characterization of the BVF and its surrounding fields of pillow lavas and metaliferous sediments. In the more detailed description presented here, we build on previously published work [Connelly *et al.*, 2012; Nye *et al.*, 2013; Kinsey and German, 2013] and keep to established names for hydrothermal vent sites. It should be noted that other works refer to this site using the alias “Piccard,” which was given after the discovery of a hydrothermal plume in the area [German *et al.*, 2010]. In this work we use the name “Beebe,” following the discovery paper [Connelly *et al.*, 2012], and as listed in the Interridge database. The chimneys described here as “Beebe-125” are also referred to as “Beebe Vents” in other works. Here we use “Beebe-125” and “Hashtag” for clarity and to describe these two distinct sites. A total of 35 sulfide samples were recovered from across the BVF (supporting information Figure S1), ranging from highly weathered and iron-oxide rich material, to zero-age sulfide chimney and beehive structures. Sulfide samples were dried under infrared heat lamps before being cut for polished thin sections. These were examined under reflected and transmitted light to establish mineralogy. X-ray diffraction was used to identify gangue minerals and secondary mineral phases. A portion of the sample, between 10 and 100 g depending on sample size, was removed and ground in a tungsten carbide mill. A large enough proportion of each sample was taken in order to avoid the “nugget effect” of gold grains in geological materials, and to provide representative samples. Despite this, the samples are inhomogeneous on the scale of centimetres, and consequently these “bulk” analyses should be approached with caution. Samples were digested using an aqua-regia, HF-HNO₃, HCl technique and ICP-AES and ICP-MS were used to determine bulk major and trace elements in the sulfide samples. Certified geological reference materials (CH-4 and RTS-1) were used to check accuracy, which was determined as 1–10% for certified elements. Precision was assessed from repeated sample digestions and was 0–10%.

3. Results

3.1. Mapping

ROV derived swath sonar mapping (gridded at a resolution of 25 cm—supporting information Figure S2), together with extensive exploration and sampling, enabled the production of a detailed geological map of the BVF mounds and surrounding terrain (Figure 2); these data were key to locating features at the site. The site is located at the summit of a dome of pillow lavas that forms part of a NE-SW oriented spur to the N-S

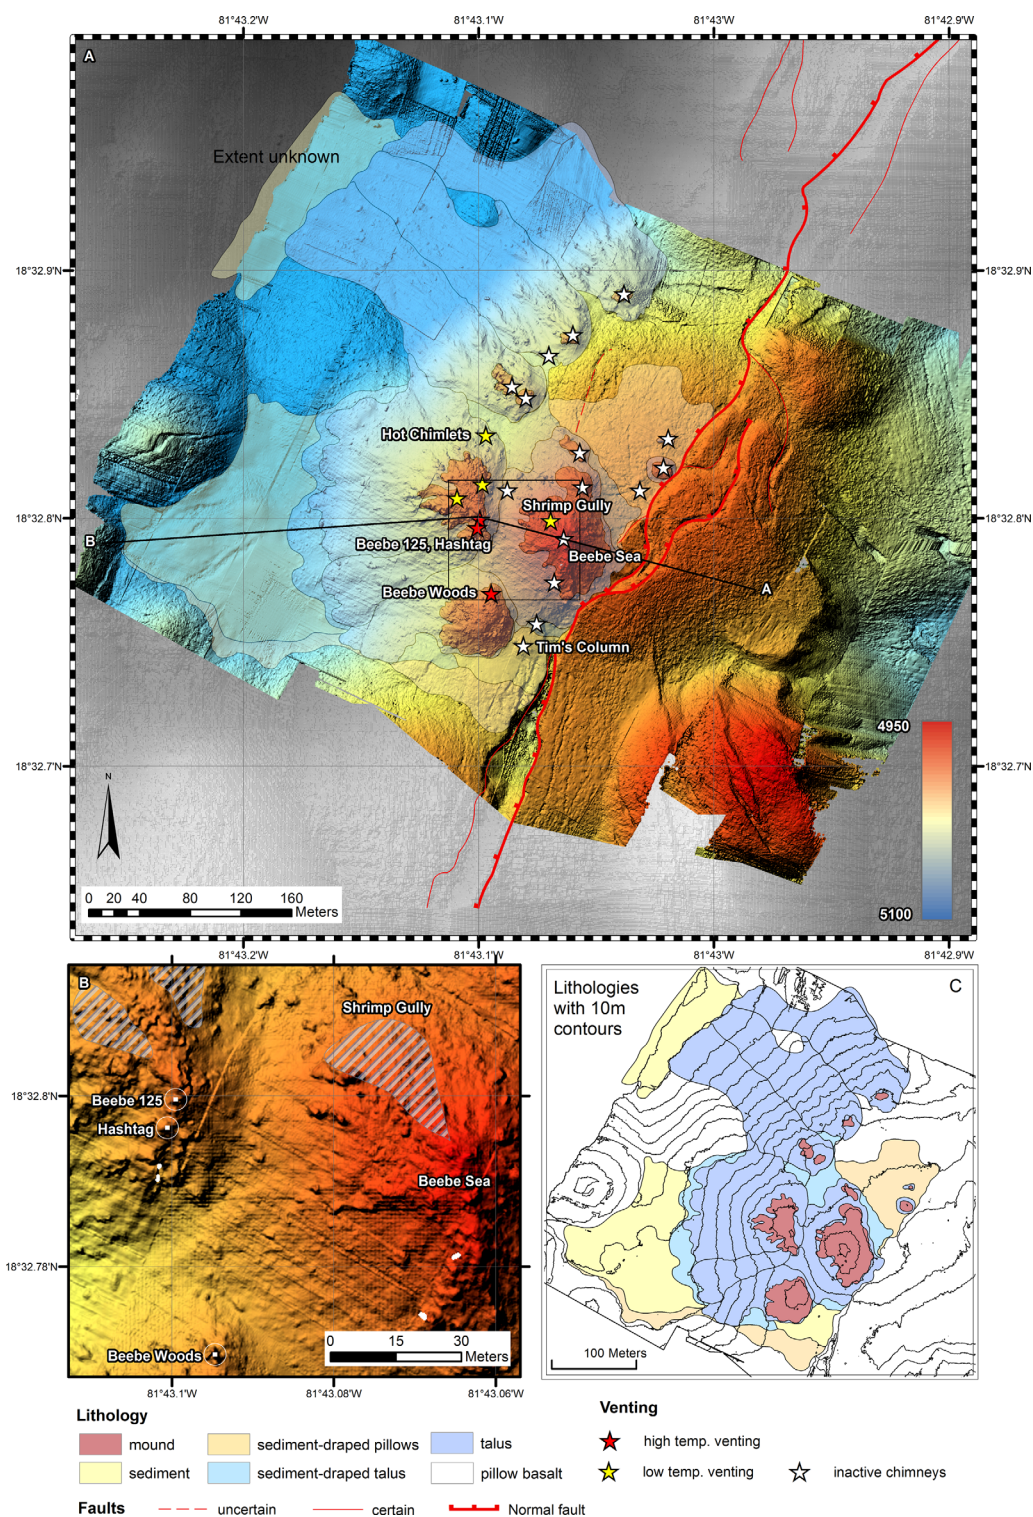

Figure 2. (a) High resolution swath bathymetry, overlain with lithological boundaries and the main features of the Beebe hydrothermal vent field. The black line AB is the line of the cross section shown in Figure 4. (b) Detailed positions of the main high temperature and several diffuse vent sites. The outline of this pane is shown in Figure 2a. (c) The mapped lithologies from high resolution swath mapping and ground-truthing with the ISIS ROV. "Sediment" refers to metaliferous sediment. The pillow basalts are variably coated with a thin veneer of pelagic sediment and this has not been mapped. "Talus" refers to sulfide talus. The "mounds" outline the solid sulfide edifices which form steep scarps, below which sulfide talus forms more uniformly sloped talus aprons. These scarps are visible on the slope-shaded map (supporting information Figure S3).

trending axial volcanic ridge, which is 3.4 km to the west. The spur abuts a regional-scale normal fault 1 km to the east of the BVF, with a throw of ~ 400 m and strike length of at least 14 km. The spur itself is dissected along its length by a prominent normal fault system with a down-throw of up to 13 m to the west. This fault defines the eastern boundary of the BVF, beyond which no evidence for hydrothermal activity, active or extinct, was observed. In the southern portion of the BVF the fault zone is marked by a single, 3–10 m wide fissure at least 5 m deep, whereas in the northern portion the fault splays and the displacement is transferred onto multiple ~ 3 –5 m high, talus-covered scarps. On the northern side of the main Beebe Sea sulfide mound a pronounced linear feature in the bathymetry indicates the presence of another splay of the fault as it emerges from beneath the main (eastern) sulfide mound and talus. Surrounding the BVF, pillow basalts comprise several volcanic domes with no obvious eruption centres which are variably covered in a thin veneer of pelagic sediment up to ~ 1 cm thick.

The BVF comprises at least six discrete sulfide mounds, three of which host active sites of focused fluid venting (Figure 2). The western-most mound (60 m wide), located on the western flank of the main pillow lava dome, hosts a cluster of chimneys called “Beebe-125” (401°C, Figure 3a) and the newly discovered “Hashtag” vent site (temperature not measured), which are both high temperature black smoker sites. These two sites are situated on a steep north-south trending ridge at the southern margin of the western-most sulfide mound (not atop the mound, as previously reported), with Beebe-125 on the northern end and Hashtag located 10 m south and 10 m deeper than Beebe 125. This mound also hosts three areas of lower temperature diffuse venting (Figure 2b, hashed areas). One of these is located on the central western flank of the mound, extends to the top of the mound, and is marked by shimmering water, anemones and bacterial mats. The other area of diffuse venting is located on top, and extending across the eastern flank of the mound, and includes a “white smoker” that vents pale-grey fluids from a crevice in sulfide rubble. This site also hosts large shrimp colonies, indicating other areas of more focussed flow. The extent of these two areas of diffuse venting is not fully understood and indeed they may be joined together. The third area of diffuse venting is known as the “Hot Chimlets” vent site, and is located on the northern flank of this mound.

The southernmost sulfide mound (60 m wide) hosts the “Beebe Woods” [Nye *et al.*, 2013] vent site (Figure 3b), which is situated on the northern margin of the mound adjacent to a steep cliff, and is a high-temperature (up to 354°C) black smoker, beehive [Fouquet *et al.*, 1993] chimney site. These vents lie 60 m south of Hashtag. Apart from Beebe Woods, no active hydrothermal activity was observed on the rest of this mound.

The largest and most prominent sulfide mound hosts the Beebe Sea vent site, and is 110–150 m wide and 40 m tall. The Beebe Sea vent site is a wide area of diffuse venting found on the northern and western flanks of the mound, including “Shrimp Gully” [Nye *et al.*, 2013]. There is no current high temperature, black smoker venting at this site.

Evidence of past hydrothermal activity is widespread, with numerous inactive chimneys located across the entire BVF. Five hydrothermally inactive sites extend the sulfide zone to the northeast of Hot Chimlets. Four of these sites comprise sulfide mounds and one consists of three distinct ~ 1 m diameter \times 3 m tall chimneys in close proximity to exposed pillow lavas. A spectacular example, located 50 m to the SW of Beebe Woods, is a single, 13 m high, 3 m wide inactive chimney, “Tim’s Column,” sited on a flat area covered by metaliferous sediment. This chimney marks the beginning of a linear trend of inactive hydrothermal structures that develop northward through Beebe Sea and ending in the centre of the BVF. A further three extinct sulfide chimney sites are located adjacent to the main fault on the north-eastern margin of the BVF.

Currently active high temperature chimneys are built on thick, solid pedestals of sulfide which are composed of many generations of chimneys (Figure 3c). These solid bases, both active and inactive, are visible on the high resolution swath bathymetry, particularly if shaded for slope angle (supporting information Figure S3), as steep scarps within the mounds below which the drape of talus displays a more uniform slope gradient. Immediately below these edifices lie numerous large pieces of broken chimney (Figure 3d). The western margin of the BVF is marked by the steep flank of the lava dome, resulting in significant mass wasting of metaliferous material to the west. This material forms aprons of talus, composed of material ranging in size from ~ 1 m blocks to sand-sized grains, which extend from the main mounds for ~ 200 m (Figure 3e). Beyond this, down slope and to the west, fine metaliferous sediment collects in depressions and flatter areas, extending the deposit for a further ~ 150 m (Figure 3f). The full extent and thickness of these metaliferous sediments remains unknown. The BVF deposit shows extreme asymmetry, with the vent site abutting

Figure 3. (a) Beebe-125 showing chimney morphology typical of Beebe-125 and Hashtag sites, looking east. The chimney in the centre of the image is ~30 cm wide. (b) Beehive chimneys of Beebe Woods looking east. White areas are shrimp, and the darker areas vent fluid that is too hot for the shrimp to colonize. Pictured chimneys are 50–100 cm wide. (c) Chimneys grow from a block of sulfide composed of amalgamated extinct chimneys, this view is of Hashtag and is 2 m wide, looking north. (d) Immediately below active and inactive vent sites are blocks of fallen chimneys, with 10 cm laser sights. (e) Further downslope from D, blocks of sulfide are no longer recognizable as chimneys, are significantly recrystallized and have lost a lot of their base metal content. Secondary alteration minerals are abundant. 10 cm laser sights. (f) More distally, fine metaliferous sediment forms thick deposits and drapes pillow lavas, sometimes with a very thin layer of back-ground sedimentation on top, as seen here. 10 cm laser sights.

a 3–13 m fault scarp in the east and with thinner aprons of mass-wasted material extending for hundreds of metres to the west (Figure 4).

3.2. Venting and Petrology

The BVF displays two main styles of high temperature venting. At Beebe-125 and Hashtag, the chimneys are slender, with highly focussed venting at the apex of each chimney. This is where the hottest temperatures were measured, at a maximum stable temperature of 401°C at Beebe-125. Locally, beehive diffusers

Figure 4. Cross section and summary of geological processes at the BVF. The section line AB is shown on Figure 2 with the seafloor being the real topography data collected during JC82, without any vertical exaggeration. Inferred solid sulfide mounds are shown in purple, which are defined by a steep gradient of the bathymetry visible on each mound (supporting information Figure S3). In pink is the draped mound talus, which displays a more consistent and gently sloping gradient and undergoes galvanic interaction, leaching base metals into the ocean. In yellow is the finer metaliferous sediment, which collects in depressions, is interbedded with the talus and displays strong stratification with coarse to fine grading within layers. The level of the basalt host rock, given by a dashed line, is inferred.

develop near the base of some chimneys. Groups of 5 or more chimneys grow from a common sulfide base, which can be several metres in breadth and height and composed of amalgamated chimneys (Figure 3c). Samples recovered included whole chimneys just 6 cm wide, to undulating sections of fallen chimneys that were tens of centimetres across. All samples of these chimneys show a very similar mineralogy, with chalcopyrite on the interior, grading out to bornite, disseminated chalcocite (Figure 5a), followed by an anhydrite/pyrite mix. The walls of the chimneys are generally 1–1.5 cm thick, with 1–8 mm of chalcopyrite and varying thicknesses of bornite and anhydrite/pyrite. Silica was present in the outer layer in minor quantities. On the very exterior of some chimneys, euhedral dog-tooth calcite crystals occur, which due to retrograde solubility are stable in the warm seawater on the exterior of the chimneys. Fluids vent almost exclusively from the apex of these chimneys and, although the chimney walls generally appear porous (e.g., Figure 5a), the first few millimetres of chalcopyrite have very little pore space and appear relatively impermeable.

At *Beebe Woods*, venting is characterized by clusters of tall “beehive” chimneys, which are consistently 50–100 cm wide and up to 30 m tall. They have a highly porous structure, with euhedral laths of pyrrhotite growing into open pore space around primary fluid pathways, sometimes with chalcopyrite in proximity to fluid conduits (Figure 5b). Away from fluid pathways, the grain-size decreases to a fine sulfide mud in a framework of dendritic and granular pyrite. Sphalerite is present as larger masses, and as disseminated blebs or rims on pyrite and pyrrhotite throughout the samples. Chalcopyrite is observed as thin bands surrounding high temperature fluid conduits. Small grains (<0.1 mm) of chalcopyrite are present as an accessory phase throughout the samples, and sometimes as mm-scale rims to sphalerite, indicating fluctuating temperatures. A wide range of fluids vent from these “beehive” structures, from relatively high temperature black fluid (measured range 296–354°C) to shimmering clear water. The shimmering water vents from the apex of some chimneys, but also from large areas of the beehive walls. The range of venting temperatures observed is consistent with the lower temperature, more zinc-rich assemblage recorded here compared to the higher temperature chimneys at Beebe-125 and Hashtag. The absence of significant chalcopyrite in these samples is striking, although it may be present in larger quantities deep within the interior of the chimneys, but was not sampled.

In contrast to the vent structures, the mound talus shows various textures and mineralogy which relate to different stages of alteration and recrystallization. Some samples show evidence of primary fluid conduits and relict pyrrhotite laths (Figures 5c and 5d), whereas others are extensively recrystallized with pyrite/marcasite masses surrounding pyrrhotite blebs (Figure 5e) and semi-massive pyrite (Figure 5f). Other samples are composed of a fine, cryptocrystalline sulphidic mud which does not polish apart from disseminated grains and thin veins of pyrite. Chalcopyrite and sphalerite are present as rare, disseminated grains, with sphalerite sometimes occurring in thin bands (Figure 5f). Atacamite and paratacamite, identified by X-ray

Figure 5. Photomicrographs of (a, b) primary sulfide and (c-f) mound talus. (a) Section through the wall of a high temperature chimney, with chalcopyrite grading to bornite and chalcocite in the upper right. To the left, the chalcopyrite continues to the fluid conduit, becoming less porous. (b) Section of beehive-type chimney from Beebe Woods. Laths of pyrrhotite grow from a porous chalcopyrite wall. The right side of the image is very fine, porous, pyrite, anhydrite and sphalerite. (c) A relict fluid conduit in mound talus. Rims of pyrite surround very fine amalgamations of anhydrite and sulfide mud (black areas). (d) Relict pyrrhotite laths, now replaced with fine sulfide mud, rimmed with pyrite. (e) Blebs of pyrrhotite being recrystallized as a pyrite/marcasite mix, with sphalerite. (f) Semimassive pyrite with bands of sphalerite and grains of chalcopyrite. py = pyrite, po = pyrrhotite, mc = marcasite, chc = chalcocite, sph = sphalerite, cpy = chalcopyrite.

diffraction, are found on the exterior of some samples, and observed as a green patchy coating on the sulfide rubble on the seafloor.

Five sediment push cores were recovered from the metaliferous sediment that had accumulated in depressions adjacent to the base of the sulfide mounds. One of these cores (sample 206-Z3) preserves a stratigraphy of several layers, each 1–5 cm thick, with a coarse sulfide base and a finer oxide top (Figure 6). These appear to have been deposited in a turbidite-like process, with coarser sulfide material deposited first followed by settling from a cloud of finer material. The presence of these sediments only downslope of the

Figure 6. Sediment core and log of metaliferous sediments from the BVF. The core shows centimetre-scale stratigraphy with thin, coarse sulfide bases and thicker, finer grained oxide tops. This indicates a turbiditic mode of deposition. Geochemical analysis of this sediment core is given in Table 1.

mounds, collection in depressions, and not on the surrounding pillow basalts, suggests mass-wasting as the likely depositional process rather than plume fall-out. These sediments are composed almost exclusively of hydrothermal material, with pyrite and minor sphalerite and chalcopyrite at the base of each bed, and iron oxide comprising the finer material on top. The surrounding pillow basalts show only a light dusting of background sedimentation, whereas the hydrothermal sediments can be greater than 30 cm thick, the length of our push-corer.

3.3. Geochemistry

The focussed chimneys at Beebe-125 and Hashtag contain up to 47 wt% Cu and 0.03–0.24 wt% Zn, whereas the beehive chimneys at Beebe Woods contain 0.5–4 wt% Cu and 0.7–14 wt% Zn (Figure 7a and Table 1). These values are consistent with the mineralogy observed at the two sites; Cu-rich at Beebe-125 and Zn-rich at Beebe Woods. The two types of chimney also show differing precious metal concentrations. The focussed chimneys of Beebe-125 and Hashtag show the lowest Au contents (0.5 to 8 ppm), whereas the beehive chimneys have a mean average of 48.8 ppm Au ($n = 8$) and a highest value of 93.6 ppm (Figure 7b). The beehive chimneys along with most of the mound rubble and the sediment core lie within the “auriferous” domain of the VMS precious metal element classification [Hannington *et al.*, 1999] (Figure 7c). The beehive chimneys also contain substantial silver, up to 500 ppm, with samples hav-

ing a high overall Au:Ag ratio compared to other seafloor sulfides (Figure 7d). Higher Au:Ag ratios of 0.24 are found only at the Logatchev vent site (supporting information Table S2) [Fouquet *et al.*, 2010].

As expected from its mineralogy of mainly Fe-sulfides, the mound talus material contains lower concentrations of base and precious metals compared to their parent chimneys, with copper and zinc both up to around 100x less (Figure 7a). Talus samples can be roughly defined as two groups – those with low Cu but relatively high Zn, and those with very low Zn and low to high Cu. The grouping of these samples indicates that they originally precipitated at the two different types of chimney. Au and Ag are around 10x less compared to the beehive chimneys, however, at an average of 10.9 ppm Au ($n = 16$), the mound material retains a substantial gold grade.

In contrast the stratified sediment core contains more base metals than the mound talus, with quantities of Cu and Zn appearing to be an average of the two chimney types (Figure 7a). The fact that they are higher in Cu and Zn than the talus suggests they form as a direct result of chimney collapse and are buried rapidly.

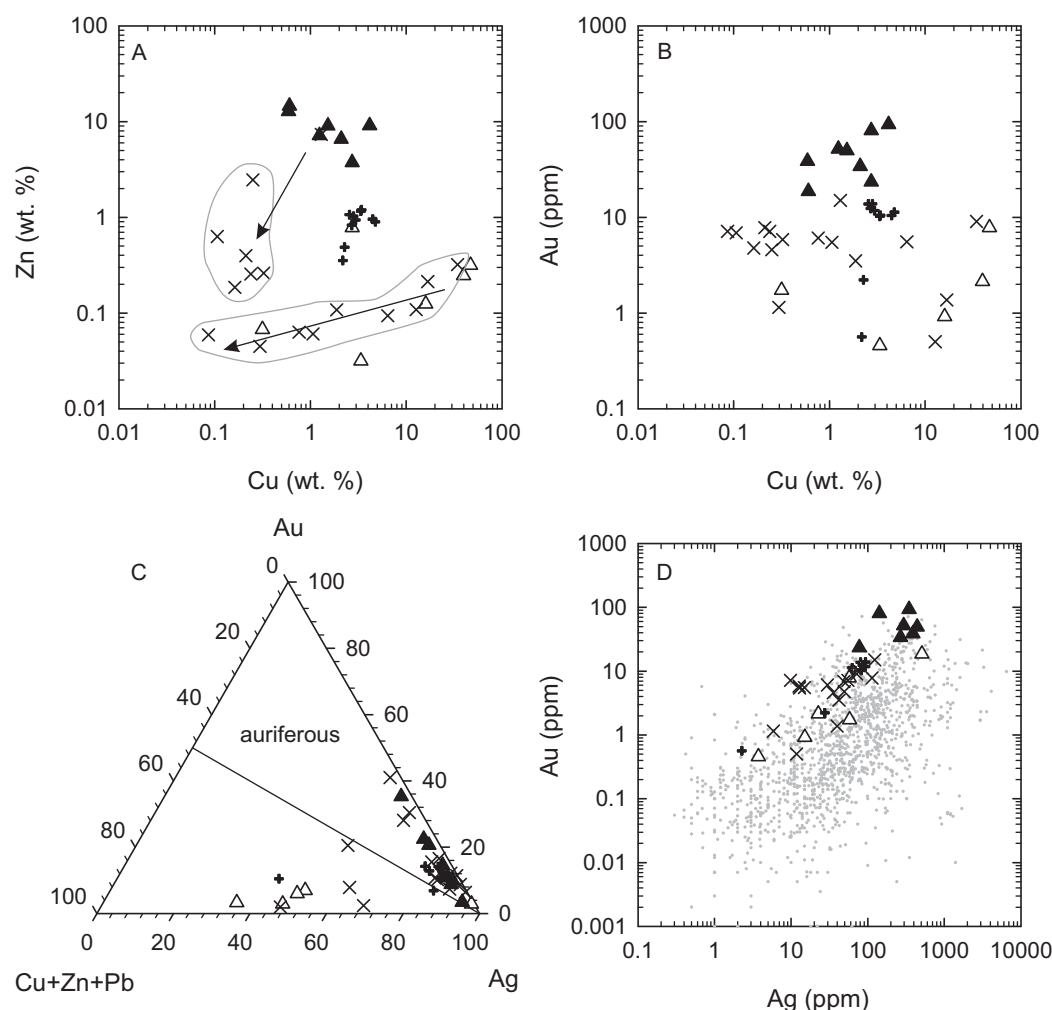

Figure 7. Results of bulk geochemical analysis of sulfide samples. In all diagrams closed triangles are of beehive chimneys, open triangles are focussed chimneys, crosses are mound talus and pluses are fine metaliferous sediment. Errors are encompassed by the symbol size. (a) Cu versus Zn. The two chimney types display very different base metal contents, with the focussed chimneys being rich in Cu whilst the beehive chimneys are rich in Zn. The mound talus show lower base metal contents, and are arranged in arrays which suggest which type of chimney they originated from. Fine sediment averages the two chimney sites. (b) Cu versus Au. The beehive chimneys show by far the highest Au content, with the fine sediment second and the mound talus third. The talus retains economically interesting Au levels despite massive loss of base metals. (c) Precious metal discrimination diagram after Hannington *et al.*, [1999]. Most samples except four of the focussed chimney, 4 talus and one fine sediment samples lie in the “auriferous” domain of the graph. (d) Ag versus Au, with the grey dots being the available data for seafloor sulfide precious metal content, compiled by Hannington *et al.*, [2004]. The BVF samples display very high Au:Ag ratios, with some of the highest Au values ever recorded for seafloor sulfides, and Ag values which are well above average in the beehive chimneys.

They also retain high Au and Ag concentrations, again appearing to average the two chimney sites (Figures 7b–7d).

In comparison to other mid-ocean vent sites (supporting information Table S2 and references therein), the BVF samples contain low Ba, Ni and Sb, whereas Fe, Au, Ag, and Au/Ag are high. Co and Se are comparable to mafic-hosted sites but generally lower than ultramafic-hosted. Sn is intermediate between ultramafic and mafic-hosted sites. Both Pb and Cu are within range of both types of vent site.

4. Discussion

4.1. Physical Conditions

The physical conditions of hydrothermal circulation and venting at the BVF are highly unusual. The BVF is ~700 m deeper than the next deepest known active hydrothermal site, at 13°N on the Mid-Atlantic Ridge

Figure 8. (a) Temperature-pressure diagram for the H_2O -NaCl system with the phase boundary for 3.2 wt% NaCl plotted. Grey triangles are the P-T conditions for known hydrothermal systems, from the Interridge database [Beaulieu *et al.*, 2013]. Compared to other high temperature systems, the BVF lies far from the phase boundary, indicating the temperature of venting fluids are not constrained by the phase boundary as at shallower sites. The star is the critical point for H_2O -NaCl at 2.3 wt% NaCl, the composition of BVF fluids, which is ~ 283 bar and $\sim 399^\circ\text{C}$. At 401 – 403°C , the BVF are 2 – 4° hotter than the critical point and are thus supercritical. Also shown is the isopleth for silica dissolution at 24 mmol/kg, the end-member composition of BVF fluids (shown in Figure 8b). Based on the observation that the BVF fluids are phase-separated, the fluid must have existed on the phase boundary at depth. The intersection of the phase boundary with the 24 mmol/kg Si isopleth suggests equilibrium at ~ 680 bars and $\sim 550^\circ\text{C}$. (b) Mg versus Si of BVF fluids. The star is bottom sea-water. Since Mg in the end-member is assumed to be 0, the end-member fluid Si concentration is 24 mmol/kg. Fluid chemistry data given in supporting information Table S1.

[Beltenev *et al.*, 2003] (Figure 8a), and also records some of the highest sustained vent fluid temperatures. With a salinity of ~ 2.3 wt.% (375 mM Cl, supporting information Table S1), at $\sim 401^\circ\text{C}$ and ~ 500 bar, the venting fluid at BVF is within the supercritical domain of the NaCl- H_2O system (Figure 8a). The Br:Cl ratio of the BVF fluids is higher than seawater (1.55×10^{-3}), at 1.73×10^{-3} , which together with the low salinity, indicates phase separation and Cl partitioning into a brine phase [Campbell and Edmond, 1989; Von Damm, 1990]. Fluid samples from all high temperature vent sites, including Beebe Woods, have the same low salinity, suggesting phase separation at depth and the same fluid upwelling beneath all active high temperature sites.

Phase separation at this depth would require temperatures of at least $\sim 500^\circ\text{C}$; 100°C hotter than the venting temperature (Figure 8a). In order to intersect the phase boundary, the fluid must be much hotter at depth, and so must have cooled significantly before venting. Shallower hydrothermal vent systems are restricted in temperature by the phase boundary [Bischoff and Rosenbauer, 1984], but at the BVF, the venting temperature is consistent with predictions that the maximum temperature of venting is limited to about 400°C by the nonlinear thermodynamic properties of water at 400 – 600°C [Jupp and Schultz, 2000, 2004]. Numerical modeling also demonstrates that deeper systems should vent fluids at about 400°C and 2 wt.% NaCl, with brine segregation and retention close to the magmatic source [Coumou *et al.*, 2009].

The crust at the Mid-Cayman Spreading Centre is thought to be exceptionally thin, with the basaltic layer described as only a few hundred metres thick, and the overall thickness of the crust, including plutonic assemblages, may be only 2 – 3 km [Stroup and Fox, 1981; ten Brink *et al.*, 2002]. To better understand the depth of hydrothermal circulation, Si

and Cl concentrations are often used as a geothermobarometer [e.g., *Foustoukos and Seyfried, 2007*], based on the assumption that Si concentration is controlled by quartz dissolution at higher temperatures. Here we take an approach similar to *Fontaine et al. [2009]*. BVF fluids show an end-member Si concentration of 24 mmol/kg (Figure 8b). Since the fluid is phase separated, it must have encountered the vapour + liquid phase boundary. Assuming Si concentrations reach equilibrium at depth, the point where the 24 mmol/kg $\text{Si}_{(\text{aq})}$ isopleth intersects the phase boundary may be taken as the P-T condition of the reaction zone, which corresponds to 680 bar and 550°C, respectively (Figure 8a). Assuming hydrostatic pressure, this indicates roughly 1.8 km to the reaction zone and requires an average geothermal gradient of 90°C/km. The majority of this cooling is expected to occur at depth, where steep geothermal gradients are indicated from numerical modeling [e.g., *Coumou et al., 2009; Hasenclever et al., 2014*]. Fluid inclusion and oxygen isotope geothermometry beneath the TAG and PACMANUS hydrothermal systems suggest much lower geothermal gradients close to the seafloor [*Petersen et al., 1998; Vanko et al., 2004; Webber et al., 2011*]. A depth of 1.8 km for hydrothermal circulation beneath the BVF is many times the thickness of basaltic crust at the Mid-Cayman Spreading Centre, and approaches the estimated total thickness of the crust. Volcanically active portions of ultra-slow spreading ridges are thought to generate crust by the emplacement of discrete magma bodies in upper mantle lithologies [*Canat et al., 1997, 2006; Yi et al., 2014*]. This is consistent with samples recovered by submersible traverses of the Cayman Spreading Centre rift walls, which recovered heterogeneously distributed basaltic, gabbroic and ultramafic lithologies, with no clear crustal structure [*Stroup and Fox, 1981*]. As such, circulating fluids beneath the BVF may interact with both gabbroic rocks and ultramafic lithologies of the lower crust. Whilst the high silica content of the BVF fluids is uncharacteristic of ultramafic-hosted systems [*Edmonds, 2010*], silica equilibration should still occur as the fluids interact with the gabbroic portions of the basement. High H_2 concentrations of as much as 20 mmol/kg [*Seewald et al., 2012*] do suggest the presence of ultramafic assemblages [*Allen and Seyfried, 2003*], although recent modeling suggests high H_2 concentrations could result from interaction with basalts at higher temperatures (>500°C), with the amount of H_2 in the fluid dependant on temperature and the water-rock ratio [*McDermott, 2015*]. The low Cu+Zn average of the BVF sulfides is comparable to mafic hosted systems (supporting information Table S2), whilst the Co and Ni content is low compared to ultramafic-hosted systems. However, Sn concentrations are intermediate between mafic- and ultramafic-hosted vents, as is the Zn/Cd ratio of 379, compared to 304 for the average of MORB sites and 614 for the average of ultramafic-hosted sites [*Fouquet et al., 2010*]. Au/Ag ratios are substantially higher than mafic systems and amongst the average values of ultramafic-hosted systems, with only Logatchev being higher [*Fouquet et al., 2010; Wang et al., 2014*]. The low Ni, high Sn and high Au are comparable to the Kairei system, where some portion of the basement was inferred to be ultramafic [*Wang et al., 2014*]. We suggest the presence of ultramafic lithologies to some degree is likely, given the exceptionally thin basaltic crust, the depth of hydrothermal circulation, ultra-slow spreading rate and high H_2 content of the fluids. The high Au/Ag ratios, similar to other ultramafic-hosted systems, suggest that these ultramafic lithologies may exert a control on the Au content of the deposit, as has been suggested for conventional ultramafic-hosted deposits [*Fouquet et al., 2010*]. Alternatively, the genesis of ultramafic-hosted systems and high Au contents could be produced from the same underlying cause, such as slow spreading rate.

4.2. Mass-Wasting, Galvanic Interaction and VMS Formation

The base-metal content of the mound rubble at the BVF is much lower than the active chimneys, with only accessory quantities of sphalerite and chalcopyrite present. The clustering of the talus samples into high zinc and high copper groups indicate their origin at the two different vent sites, and subsequent loss of Cu and Zn, or that these samples never contained high quantities of Cu and Zn. The former case suggests that leaching and/or preferential dissolution of Cu-sulfides and sphalerite has occurred. Such changes in mineralogy can be explained by galvanic interaction between sulfide phases [e.g., *Liu et al., 2008*], where the rate of leaching of Cu and Zn is substantially increased when chalcopyrite and sphalerite are in contact with pyrite [*Mehta and Murr, 1983*]. Chalcopyrite in particular was rarely seen in direct contact with pyrite in the mound talus (Figure 5f). The rarity of these base metal sulfides and the 100x reduction in base metal content seen in the mound talus compared to zero-age chimneys (Figure 7a) suggest this process occurs rapidly, leaving little base metal to be incorporated into the deposit on burial of the talus. The dissolution of Cu-sulfides has been linked to the formation of atacamite and paratacamite gossans at TAG [*Hannington, 1993*]. Whilst we do find these phases on the exterior of some talus blocks at the BVF, they do not occur as extensive gossans, perhaps due to ongoing sediment transport downslope.

Figure 9. Conceptual model for the influence of steep topography on VMS deposit formation, as indicated by observations from the BVF. (a) A sulfide deposit on flat topography builds a mound in layers that are successively buried. Diffuse venting from the mound, which is suggested to constitute to 70% of total fluid flux [Humphris and Cann, 2000], keep Cu- Zn- and Pb-sulfide phases in more stable conditions, whilst precipitating ore phases which cement the talus clasts. Consequently, the mound talus represents a significant proportion of the base metal content of the deposit. (b) With steep topography, a large proportion of the mound talus is rapidly transported away from higher temperature conditions, including diffuse venting, placing it under conditions in which sulfide phases can rapidly dissolve and undergo galvanic interaction. The mound talus loses the majority of its base metal content. Mass-density currents deposit finer metaliferous sediments in a distal setting, and burial is fast enough to preserve base metals. (c) The resulting VMS deposit constitutes a sulfide lens and stockwork, which are the main ore body, but the lens is smaller than it would have been on gentler terrain. Adjacent, down-dip, is a massive pyrite lens which is barren of base metals but may preserve precious metal content. More distally are metaliferous sediments, which will vary in composition due to background sediment influx. The final grade of these fine sediments depends on the ratio of metaliferous to background sedimentation.

them from seawater. Instead, mass wasting would produce lenses of massive pyrite/pyrrhotite with a reduced base metal content (Figure 9), although they could retain economically interesting grades of precious metals. These lenses are equivalent to the copper-poor pyrite breccias seen on the exterior of the TAG mounds [Hannington *et al.*, 1998] and at other sites.

Another mass-wasting product at Beebe is the fine metaliferous sediment found at the bottom of the talus slopes and filling depressions that, in one core, shows stratified layers resembling turbidite deposits (Figure 6). This suggests formation by rapid deposition and burial, following the collapse and mass wasting of chimneys which facilitates transport of finer material in a mass-density current. These sediments are not as depleted in base metals as the talus material, instead they appear to average Cu and Zn concentrations from the two types of vent structure (chimneys and beehives). Metal loss from these fine sediments must occur at a much slower rate than from the talus material, perhaps due to their lower permeability, and it is

This loss of base metals raises questions with respect to the overall grade and tonnage of the resulting VMS deposit and the release of base metals into the ocean. Collapse of a chimney immediately places the ore sulfides into oxidizing conditions under which they are not stable. If a large proportion of the Cu- and Zn- bearing minerals are lost from the talus material, then most of the overall grade of the deposit must come from subseafloor precipitation, talus that remains proximal to venting and is buried quickly, or chimney structures that do not collapse but are overgrown and incorporated into the mound *in-situ*. Individual vent sites within the field need to be long-lived in order to build a sufficient mound suitable for the preservation of the ore minerals. Instead of being a primary ore material, the role of altered talus may be to provide a high permeability framework into which ore sulfides can later be precipitated as it is buried and incorporated into the interior of the mound, as part of the “zone refining” model of Eldridge *et al.* [1983]. This variety in precipitation, mass-wasting, alteration, burial and reprecipitation processes is consistent with the ore textures observed in VMS deposits, from preserved chimneys and brecciated primary chimney sulfides to sulfide sands and brecciated pyrite clasts cemented by ore sulfides [e.g., Eldridge *et al.*, 1983; Brown and McClay, 1998; Galley *et al.*, 2007].

The steep topography at the BVF facilitates rapid transport by mass wasting of material away from the active hydrothermal vent site. It is unlikely this material will contribute in a significant way to the base metal content of the deposit unless individual mass wasting events are thick enough to effectively bury ore phases and isolate

Figure 10. Au versus total base metal content (Cu + Zn + Pb in wt. %). Symbols as in Figure 7, with the grey dots being global VMS deposits in the geological record. Diagram after Mercier-Langevin *et al.* [2011]. Auriferous domains are defined either as having a greater gold grade than the geometric mean + geometric standard deviation of all VMS deposits, which is 3.46 ppm, or by having a greater Au content in ppm than total base metal content in wt. %. Only a handful of VMS deposits lie in either of these auriferous domains. Almost all of the BVF lie in the auriferous domain of the diagram, with most having a greater Au grade than total base metal content. The average of all BVF samples is given by the star. Although this compares hand specimen-scale samples to whole deposits, it gives an indication that the resulting deposit as a whole would be auriferous. In particular, the Au:base metal ratio of the mound talus is exceptionally high due to base metal loss.

extremely Au-rich compared to base metals, likely resulting from the leaching of base metals into seawater. The metaliferous sediments and Beebe Woods chimneys have the highest Au grade, comparable to some of the most Au-rich VMS deposits (Figure 10). The Beebe Woods chimneys in particular are also rich in Ag, although the deposit has a low Ag:Au ratio overall (Figure 7d).

To better understand the likely metal content of Beebe requires a calculation of overall tonnage. We calculated the grade and tonnage of the Beebe mounds and talus material using a volume estimation of the sulfide material that lies above the level of the pillow basalts. We acknowledge there is presumably a mineralized stockwork zone beneath the BVF which we have not included but would add some additional tonnage. In addition, VMS deposits in the geological record show grading of metal content, particularly Cu/Zn ratio, from the surface to the interior, culminating in a Cu-rich inner mound and stockwork [Lydon, 1984], which we cannot account for. There is also considerable variation in Au grades, with seafloor sulfide mounds showing more Au-rich exteriors [e.g., Hannington *et al.*, 1995; Petersen *et al.*, 2003]. We therefore use estimates of total metal content and other parameters (Table 2), based primarily on the fine sediments which appear to average both chimney types. We calculate the BVF metal content to be in the region of 1 million tonnes, with a tentative 22,000 tonnes of copper and 59,000 to 172,000 oz Au. Such values would suggest the BVF is a small VMS in commercial terms but contains a substantial amount of Au for its size.

At the BVF, the same high temperature, low salinity fluid is emitted from two vent sites only 60 m apart, Beebe-125 and Beebe Woods, yet one forms Au-rich beehive chimneys while the other is relatively Au-poor (Figure 7b). This strongly suggests that, at the BVF, chimney morphology controls Au-precipitation and, therefore, the generation of an auriferous VMS. The beehive chimneys at Beebe Woods are highly porous, allowing for a high surface area and greater seawater mixing within the chimney [Fouquet *et al.*, 1993]. The pH increase, temperature drop and fO_2 increase associated with seawater mixing all lead to gold precipitation [e.g., Stefansson and Seward, 2004; Pokrovski *et al.*, 2015]. These rapid changes in fluid chemistry

likely that these deposits would represent an economically interesting horizon if preserved in the geological record. These fine sulphidic sediments are equivalent to distal ores preserved in VMS deposits, for example at Yaman Kasy in the southern Uralides, where ores with rhythmic oxide/sulfide bands can be found [Herrington *et al.*, 2005].

4.3. Metal Content

None of the BVF samples contain any significant Pb mineralization, and as such, the BVF can be classified as a Cu or Cu-Zn VMS deposit [after Large, 1992]. The best estimate of the overall Cu:Zn ratio may come from the metaliferous sediments, which appear to reflect the average of the different types of chimneys and their compositions, at 69–85% Cu (Cu/Cu + Zn + Pb). Such copper-rich deposits are typical of a low tonnage, mafic-dominated VMS [e.g., Galley *et al.*, 2007].

The BVF sulfides are some of the most Au-rich that have been recovered from the seafloor and exhibit high Au to base metal ratios (Figure 10). The mound talus in particular, is

Table 2. Parameters Used in Metal Content Calculation

Input Parameters	Value	Value (Conservative)	Units	Source
Sulfide Volume	218000		m ³	<i>Kinsey and German [2013]</i>
Density of pyrite	5.01		g/cm ³	
Porosity	30		%	e.g., <i>Tao et al. [2013]</i>
Copper content	3		wt. %	Estimated from sediment samples
Au content	7	2	ppm	Estimated from sediment samples
Calculated: Tonnage	0.76		Million tonnes	
Copper	22,936		tonnes	
Gold	172,635	49,324	oz	

together with the high surface area of the chimney interior may facilitate efficient precipitation of precious metals in comparison to chimneys that consist of one primary fluid conduit and maintain low seawater mixing proportions up to the vent orifice. A similar process was recorded for white smoker chimneys at the TAG hydrothermal field, although the interpretation

there was that the high Au values result from reworking of Au from the interior of the mound and repeated concentration within the chimneys [Hannington *et al.*, 1995]. This repeated processing by chimney structures was thought to lead to an overall Au loss from the system, since each time a proportion of the gold is vented, resulting in a Au-poor deposit. However, we suggest that at Beebe, due to the steep topography, mass wasting rapidly moves material away from hydrothermal activity, resulting in preservation of at least a proportion of the high Au grades.

Another aspect of the BVF that might control chalcophile element concentrations, including gold, is the proximity of upper-mantle ultramafic lithologies. Since mid-ocean ridge basalts are generally sulphur-saturated, they have a limited capacity to dissolve the sulfide blebs in the upper mantle and so chalcophile elements are preferentially retained in the mantle [Peach *et al.*, 1990]. This may be particularly important at the Cayman Trough, where the spreading rate is only 11 mm/yr, leading to the generation of one of the lowest melt thicknesses in the world [White *et al.*, 2001]. At such a low rate of melt generation, and with a partition coefficient for Au between sulfide and silicate melt of >15,000 [Peach *et al.*, 1990], the vast majority of the gold would be expected to be retained in the mantle sulfides. The concentration of gold in the upper mantle is thought to be considerably higher (1 ppb) [Salters and Stracke, 2004] than MORB (0.34 ppb) [Webber *et al.*, 2013]. Given our interpretation of the subsurface at Beebe includes fluid interaction with mafic and ultramafic lithologies at depth, hydrothermal interaction with the sulfides in the upper mantle rocks provides an alternative mechanism for the release of chalcophile elements.

Most Au-rich VMS deposits in the geological record are associated with a bi-modality in host-rock composition in a back-arc or arc setting, or show evidence for shallow formation resulting in boiling, or have been deformed leading to significant post-depositional enrichment in Au [Dubé *et al.*, 2007; Mercier-Langevin *et al.*, 2011]. The BVF fulfils none of these associations yet is auriferous. However, there is growing evidence that vent sites situated on slow-spreading mid-ocean ridges, especially those ultramafic hosted, are particularly gold-rich [Münch *et al.*, 2001; Tao *et al.*, 2011; Nayak *et al.*, 2014; Fouquet *et al.*, 2010; Wang *et al.*, 2014]. In this geotectonic setting, we suggest the availability of gold-rich sulfide blebs in the reaction zone and, vitally, the precipitation of gold in beehive chimney structures has enabled the formation of an auriferous sea floor massive sulfide deposit.

5. Summary

The BVF is a basalt-hosted hydrothermal system with several unusual and interesting characteristics. It is hosted in an ultra-slow, ultra-deep spreading centre with exceptionally thin basaltic crust, and vents phase separated, low-salinity, supercritical fluid. It is one of only two sites at this time known to vent supercritical fluid, the other being Turtle Pits at 5°S on the Mid-Atlantic Ridge [Koschinsky *et al.*, 2008]. One of the most striking features and on-going processes at the BVF is the steep topography and the influence this has on the growth of the mound and preservation of the deposit (Figure 4). This shows that topography alone can have a significant impact on the metal content and mineralogy of a sulfide mound and therefore VMS deposits in general. We also show that the BVF is an exceptionally Au-rich hydrothermal deposit. Au precipitation at the BVF appears to be controlled by chimney morphology, while the presence of gold-rich sulfide

blebs in the reaction zone may increase the overall availability of gold. The tectonic setting, host rock and depth are not thought to be conducive to forming Au-rich VMS deposits in the geological record. The observation that two different chimney sites, just 60 m apart, venting the same fluid but precipitating assemblages with highly contrasting Au concentrations mirrors observations from VMS districts, where the Au content of neighbouring deposits can be similarly contrasting [Hannington *et al.*, 1999; Mercier-Langevin *et al.*, 2011]. In these ways, Beebe offers an important insight into the formation of sulfide deposits, both past and present, as well as processes of hydrothermal circulation beneath the seafloor.

6. Conclusions

The BVF hosts high temperature, low salinity venting that is supercritical at the vent orifice. Phase separation occurs at depth, with Si and Cl concentrations indicating reaction zone P-T conditions of 680 bar and 550°C.

The high temperature, focussed-flow hydrothermal chimneys are composed of a copper-dominated chalcopyrite/bornite assemblage, while the diffuse-flow hydrothermal “beehives” are rich in Zn, Au and Ag. Precious metal concentrations in the precipitates are controlled by chimney morphology, where beehive chimneys allow increased seawater mixing within the chimney structure and subsequent precipitation of gold.

The mound talus has lost the majority of its base-metal content to the ocean as a result of galvanic interaction between sulfide phases and oxidized seawater. This has left the talus almost entirely composed of pyrite, with copper and zinc secondary phases such as paratacamite on the exterior of some samples. The talus does retain some precious metal content.

The fine metaliferous sediments contain higher concentrations of both base and precious metals than the mound talus, and appear to represent an average composition of the main high temperature vent sites. The lack of significant pelagic sediment input results in distal hydrothermal sediments containing ore-grade levels of metals.

The BVF represents a mafic-dominated, highly auriferous, Cu-Zn VMS deposit in the making. Its unusually high gold content and high Au:Cu ratios are comparable to some of the most gold-rich VMSs known in the geological record.

Acknowledgments

This study was funded by the Natural Environment Research Council (NERC), UK, grant NE/I01442X/1. We gratefully acknowledge NERC staff and scientists aboard the RRS James Cook. We are grateful for the detailed and insightful comments of the reviewers Sven Petersen and an anonymous reviewer. Geochemical data used in this study are available in Table 1 and supporting information Table S1. Further information about samples available on request. Bathymetry data products available in supporting information.
