Abstract. Stable nitrogen isotope composition (δ15N) offers new opportunities to address the long-standing and ongoing controversy regarding the origins of ambient ammonia (NH3), a vital precursor of PM2.5 (particulate matters with aerodynamic diameter equal or less than 2.5 µm) inorganic components, in the urban atmosphere. In this study, the δ15N values of NH3 samples collected from various sources were constrained using a novel and robust chemical method coupled with standard elemental analysis procedures. Independent of the wide variation in mass concentrations (ranging from 33 (vehicle) to over 6000 (human excreta) µg m−3), different NH3 sources have generally different δ15N values (ranging from −52.0 to −9.6 ‰). Significantly high δ15N values are seen as a characteristic feature of all vehicle-derived NH3 samples (−15.4 ± 3.8 ‰), which can be distinguished from other sources emitted at environmental temperature (−29.1 ± 1.7, −37.8 ± 3.6, and −50.0 ± 1.8 ‰ for livestock, waste, and fertilizer, respectively).

The isotope δ15N signatures for a range of NH3 emission sources were used to evaluate the contributions of the different sources within measured ambient NH3 in Beijing, using an isotope mixing model (IsoSource). The method was used to quantify the sources of ambient NH3 before, during, and after the 2014 Asia-Pacific Economic Cooperation (APEC) summit, when a set of stringent air quality control measures were implemented. Results show that the average NH3 concentrations (the overall contributions of traffic, waste, livestock, and fertilizer) during the three periods were 9.1 (20.3, 28.3, 23.6, and 27.7 ‰), 7.3 (8.8, 24.9, 14.3, and 52.0 ‰), and 12.7 (29.4, 23.6, 31.7, and 15.4 ‰) µg m−3, respectively, representing a 20.0 % decrease first and then a 74.5 % increase in overall NH3 mass concentrations. During (after) the summit, the contributions of traffic, waste, livestock, and fertilizer decreased (increased) by 56.7 (234.2), 12.0 (−5.0), 39.4 (120.8), and −87.7 % (−70.5 %) when compared with periods before (during) the summit, respectively, signifying that future NH3 control efforts in megacities like Beijing should prioritize traffic sector as well as livestock breeding. The results show that isotope ratio measurements of NH3 to be a valuable tool to quantify the atmospheric sources of NH3 in urban atmospheres.

1 Introduction

For more than a century, the Haber–Bosch process has been meeting the Earth’s increasing demand for grain and protein through nitrogen fertilizer (Erisman et al., 2008; Sutton et al., 2011). But unintentionally, increasing the application of ammonia (NH3) and its derivatives as fertilizer has altered the composition of the atmosphere (Fowler et al., 2009). Fertilizer application merged with livestock production is the...
largest contributor of NH$_3$ emissions (Aneja et al., 2008), which cause cascading effects on human health, ecosystems, and climate (Galloway et al., 2003).

Whilst the overwhelming contribution of agricultural activities to the global and regional NH$_3$ budgets is well accepted, a large number of observations show that the ambient levels of NH$_3$ concentration in cities are comparable with, or even higher than, those in rural areas (e.g., Cao et al., 2009; Meng et al., 2011; Singh and Kulshrestha, 2014; Zbieranowski and Aherne, 2012). Given that the atmospheric behavior of NH$_3$ is characterized by a short lifetime (1–5 days or less) (Warneck, 1999), low transport height, and relatively high dry deposition velocity (Asman and van Jaarsveld, 1992), high rural NH$_3$ emissions do not generally influence urban areas strongly in the gaseous phase unless reacting with acidic gases locally to form particulate NH$_4^+$ (Flechard et al., 2013). Therefore, other non-agricultural sources must exist in urban areas (Chang, 2014; Sutton et al., 2000). Some authors argue that gasoline-powered vehicles equipped with three-way catalytic converters (TWCs) and diesel-powered vehicles fitted with the selective catalytic reduction system (SCRs) are a major contributor of non-agricultural NH$_3$ (Burgard et al., 2006; T. Liu et al., 2014; Perrino et al., 2002). In the UK, for example, it is estimated that 15 % of the national NH$_3$ emissions originate from non-agricultural activities (Sutton et al., 2000), and 5–6 % of the total NH$_3$ emissions in the USA are derived from vehicles, with almost all the remaining NH$_3$ coming from agricultural processes (Kean et al., 2009). Based on a “bottom-up” methodology, a city-specific non-agricultural NH$_3$ emission inventory for 113 Chinese cities was recently established (Chang, 2014), in which traffic (32.2 %) was identified as the largest NH$_3$ emission source. At the global scale, non-agricultural NH$_3$ emissions are 1 or 2 orders of magnitude smaller than the mass flux of gaseous NH$_3$ between the Earth’s surface and the atmosphere, which totals more than 50 Tg yr$^{-1}$ (Schlesinger and Hartley, 1992). Non-agricultural activities, however, are highly concentrated in urban areas and, therefore, could be supposed to be significant sources of NH$_3$ in cities (Chang et al., 2012). Given the important role of urban NH$_3$ emissions to form PM$_{2.5}$ (particulate matters with aerodynamic diameter equal or less than 2.5 µm), NH$_3$ emission reduction has been regarded as the key to curb severe haze pollution in Chinese megacities (Ye et al., 2011; Wang et al., 2011, 2013).

Although isotopic techniques have been extensively accepted as a useful tool for source apportionment of gases and PM (e.g., Cao et al., 2011; Felix et al., 2012; J. Liu et al., 2014; Rudolph et al., 1997; Wang et al., 2016; Xiao et al., 2012, 2015; Xiao and Liu, 2002), there have been few studies to date in terms of directly observing or quantifying the contribution of non-agricultural NH$_3$ in the atmosphere (Felix et al., 2014; Liu et al., 2008). Greater scientific attention and regulatory efforts have been given to nitrogen oxides (NOx = NO + NO$_2$) (Felix et al., 2012; Michalski et al., 2014; Walters and Michalski, 2015; Walters et al., 2016, 2015) and sulfur dioxide (SO$_2$) (Barros et al., 2015; Giesemann et al., 1994; Habicht and Canfield, 1997; Zheleznitskaya et al., 2014). Also, the conventional method for analyzing $\delta^{15}$N, using elemental analyzer (EA) combustion with isotope-ratio mass spectrometry (IRMS), normally requires more than 20 µg N for a single solid sample, which poses a considerable challenge for passive sampling devices (Skinner et al., 2006). To overcome this technical restriction, a landmark paper was published by Felix et al. (2013), in which they tried to combine the bromate (BrO$_3^-$) oxidation of NH$_3$ to NO$_2^-$ with microbial denitrifier methods (bacteria converts NO$_2^-$ to N$_2$O) to permit the N isotopic analysis of low concentration NH$_4^+$ passive samples, featuring the high throughput of sample mass and low toxicity of reagents. However, the microbial denitrifier they used needs careful cultivation and maintenance, which is time-consuming and also may present a challenge for many isotope laboratories. Recently, a novel and robust chemical method for $\delta^{15}$N–NH$_4^+$ at natural abundance has been developed (D. Liu et al., 2014), which has major advantages over previous approaches: (i) substantially simplified preparation procedures and reduced preparation time particularly compared to the methods in which diffusion or distillation is involved, since all reactions occur in the same vial and separation of NH$_4^+$ from solution, is not required; and (ii) greater suitability for low volume samples including those with low N concentration, having a blank size of 0.6 to 2 nmol.

The 2014 Asia-Pacific Economic Cooperation (APEC) summit, another major international event after the 2008 Olympic Games, was hosted in Beijing on 3–12 November. To ensure good air quality and traffic flow during the APEC Summit, a set of stringent measures to control atmospheric pollutants, including regulating vehicle travel (restricting traffic based on the odd and even number plate rule), delaying winter heating (for a week), suspending coal-based industries, and closing construction sites, were implemented in Beijing and its neighboring provinces over a month before and during the APEC summit (Chen et al., 2015; J. Li et al., 2015; Tang et al., 2015; Xu et al., 2015b). This provided a unique city-wide experiment to isotopically examine the response of various NH$_3$ sources to such comprehensive and intensive mitigation efforts. In the present study, the isotopic signatures of various NH$_3$ sources in China were determined for the first time. Moreover, the ambient NH$_3$ concentrations and their isotopic compositions were investigated before, during, and after the APEC control period in Beijing. Based on the isotopic signatures of major sources we developed, a stable isotope mixing model was used to quantify the contributions of each NH$_3$ source in order to examine the effect of the control measures.
2 Methodology

2.1 Ambient NH$_3$ monitoring

The Adapted Low-Cost Passive High Absorption (ALPHA) samplers (Centre for Ecology and Hydrology, Edinburgh, UK), one of the most widely recognized passive sampling devices (PSDs) (Puchalski et al., 2011; Tang et al., 2001; Xu et al., 2015a), were used to collect ambient NH$_3$ in this study. The ALPHA sampler is a circular polyethylene vial (26 mm height, 27 mm diameter) with one open end. The vial contains a position for a 25 mm phosphorous acid-impregnated filter and a PTFE (polytetrafluoroethylene) membrane for gaseous NH$_3$ diffusion. In the current study, triplicate ALPHA filters were used to collect NH$_3$ for IRMS at weekends (from Saturday to Monday) or weekdays (from Monday to Saturday) on the roof of a four-story building (12 m a.g.l.) on the campus of the China Agricultural University (CAU), Beijing (116.289° E, 40.032° N), before (18–20, 20–25, 25–27 October, 27 October–1 November, 1–3 November), during (3–8, 8–10, 10–15 November), and after (15–17, 17–22, 22–24, 24–29 November) the APEC summit (normally at 08:00 local time). The site of the CAU campus represents a general urban background with relatively low-rise buildings in the surrounding area, ca. 16.3 km northwest of Tiananmen Square (Fig. 1). In this study, the three filters of one sampling event were combined for a single analysis. Hourly mass concentrations of gases (CO, SO$_2$, NO$_x$, and O$_3$) and PM$_{2.5}$ in Beijing are averaged from the data obtained from the 14 state-controlled environmental monitoring stations across the city (http://datacenter.mep.gov.cn/).

2.2 NH$_3$ source sampling

The Ogawa passive sampling device (Ogawa & Co., FL, USA) is another popular PSD that has been successfully applied in the USA (Butler et al., 2015; Puchalski et al., 2011) and China (Chang et al., 2015; Meng et al., 2011) to determine the time-integrated NH$_3$ concentrations. The Ogawa PSD is a double-sided passive diffusion sampler equipped with a diffusive end cap, followed by a stainless-steel screen, and a 14 mm quartz filter impregnated with phosphoric acid by the manufacturer. In this study, the Ogawa PSDs were used to collect NH$_3$ emitted from sources for isotopic analysis.

Six NH$_3$ emission sources were involved in this study, i.e., livestock (two pig sties), fertilizer volatilization (laboratory simulation of NH$_3$ volatilization from urea-fertilized soil), human excreta (septic tanks of a residential building and a teaching building), waste water (sewage water treatment plant), solid waste (municipal waste transfer stations in a residential community and an educational area), and vehi-

Figure 2. Field photos of a solid waste container in the solid waste transfer station we used for source sampling at Fudan University. Before sampling, an Ogawa passive sampler for NH\(_3\) is attached on a plastic strip (1.5 m in length). The sampler is fitted into the container through the holes (shown on the right panel).
pling period of 2 h could provide sufficient N–NH₃ as well as avoid potential fractionation. Another example is the on-road traffic source. The δ¹⁵N–NH₃ values of weekly (−11.9; −11.2 ‰), semi-monthly (−11.7; −12.5 ‰), and monthly samples (−12.0 ± 1.8 ‰; n = 4) in the exit of Handan tunnel were almost identical, suggesting that passive NH₃ collection is an effective approach for isotopic analysis procedures.

2.3 Stable isotope analysis

A newly developed chemical method for δ¹⁵N–NH₄⁺ of low NH₄⁺ samples was used in the current study. The detailed analytical procedures are given elsewhere (D. Liu et al., 2014). Briefly, this method is based on the isotopic analysis of N₂O, which is much less abundant in the atmosphere than N₂ and thus causes minimal atmospheric contamination. Filter samples were firstly soaked with ultra-pure water (18.2 MΩ cm). Concentrations of NH₄⁺ were then analyzed using an ion chromatographic system (883 Basic IC plus, Metrohm Co., Switzerland) equipped with a Metrosep C4/4.0 cation column. The eluent was 1.0 mM HNO₃ + 0.5 mM PDA. The detection limit for NH₄⁺ was 0.0028 mg L⁻¹. After the measurement of the NH₄⁺ concentration, NH₄⁺ in every sample was initially oxidized to NO₂⁻ by hypobromite (BrO⁻) in a vial. NO₂⁻ was then quantitatively converted into N₂O by hydroxylamine (NH₂OH) under strongly acid conditions. The produced N₂O was analyzed by a purge and cryogenic trap system (Gilson GX-271, IsoPrime Ltd., Cheadle Hulme, UK) coupled to an IRMS (PT–IRMS) (IsoPrime 100, IsoPrime Ltd., Cheadle Hulme, UK) at the Stable Isotope Ecology Laboratory of Institute of Applied Ecology, Chinese Academy of Sciences.

Isotope ratio values are reported in parts per thousand relative to atmospheric N₂ as follows:

\[ \delta^{15}N(\text{‰}) = \frac{\left( {^{15}N/{^{14}N}_{\text{sample}}} \right) - \left( {^{15}N/{^{14}N}_{\text{N}} \right)} {\left( {^{15}N/{^{14}N}_{\text{N}} \right)}} \times 1000. \]  

Three international NH₄⁺ standards (IAEA N1, USGS 25, and USGS26 with δ¹⁵N values of +0.4, −30.4, and +53.7 ‰, respectively) were used to correct for the reagent blank and drift during isotope analysis of the produced N₂O. The standard deviation of δ¹⁵N measurements is less than 0.3 ‰. Moreover, to enhance our confidence in the results determined by the PT–IRMS method, the δ¹⁵N values of fertilizer-, vehicle-, human excreta-, and solid waste-derived NH₃ were also examined by the EA-IRMS method at the Shanghai Institutes of Life Sciences, Chinese Academy of Sciences (Supplement Sect. S1).

2.4 Isotope mixing model

Stable isotope mixing models offer a statistical framework to estimate the relative contributions of multiple sources to a mixture, such as food-web structure, plant water use, air pollution, and many other environments (Cole et al., 2011; Dai et al., 2015; Jautzy et al., 2015; Wang et al., 2016). A common problem, however, is having too many possible sources relative to isotopes to allow unique linear mixing solutions based on mass-balance equations. To this end, Phillips and Gregg (2003) developed the model IsoSource, which solves iteratively for feasible mixing solutions, and has been well tested in numerous studies (e.g., Cole et al., 2011; Dai et al., 2015; Jautzy et al., 2015; Wang et al., 2016). The model does not generate exact values for proportional contributions of each source, but instead provides a range of possible contributions or feasible solutions. The IsoSource addresses every possible combination of source proportions (summing to 100 %) incrementally (e.g., 1 %), then calculates the predicted isotope value for each combination using linear mass-balance equations. These predicted values are then examined to determine which ones fall within some tolerance range (typically 0.1 ‰) of the observed consumer isotope value, and all of these feasible solutions are recorded. The IsoSource model is available at https://www.epa.gov/eco-research/stable-isotope-mixing-models-estimating-source-proportions. Considering the large number of possible sources for ambient NH₃, we use multiple lines of evidence (prior information) to constrain the emission sources in the mixing model analysis: (1) there was no crop harvest activity in the North China Plain (NCP) during the APEC summit in Beijing. Besides, harvesting forests for fuelwood and timber has nearly disappeared in Beijing. Therefore, the contribution of biomass burning is considered minimal; (2) Beijing is 150 km inland from the Bohai Sea (the nearest sea) via Tianjin Municipality in the southeast. Therefore, the marine source in Beijing can be neglected; and (3) previous work indicated that miscellaneous NH₃ sources like pets and household products are minor NH₃ emissions in Beijing urban areas (Chang, 2014), which thus can be largely neglected.

In conclusion, ambient NH₃ in Beijing during our study period has been shown to be due to four main sources: livestock production, N-fertilizer application, on-road traffic emissions, and waste-derived emissions. The δ¹⁵N average values for these four NH₃ emission sources will be built and served as the baseline input to the IsoSource. For the traffic source, given that the relatively larger difference in terms of their δ¹⁵N values in different seasons (see Table 1), the wintertime average value of δ¹⁵N was used in this study because the APEC summit was held during winter. In brief, the N isotopic signatures for the sources of waste, livestock, traffic, and fertilizer are set as −37.8, −29.1, −16.5, and −50.0 ‰, respectively (Tables 1 and S1). The source increment and mass-balance tolerance parameter values of 1 % and 0.1 ‰, respectively, were applied. Model output files include all the feasible source combinations, with histograms and descriptive statistics on the distributions for each source. Results are expressed as box-and-whisker plots for these distributions.
3 Results and discussion

3.1 Isotopic signatures of NH₃ emission sources

Using N isotope as a tool to discriminate the contribution of various sources to ambient NH₃ concentration requires (i) well-established N isotopic compositions of NH₃ emission sources and (ii) well-constrained N isotope fractionation to allow separating different sources. In total of 44 NH₃ source samples in this study, δ¹⁵N values and NH₃ concentrations of these samples ranged from −52.0 to −9.6‰, and 33 to 6211 µg m⁻³, respectively (all data are presented in Table S1). These NH₃ sources can be classified into four categories, i.e., fertilizer, livestock, traffic, and waste. For most sources, there was no significant difference in terms of their δ¹⁵N values in different seasons (Table 1), indicating the effectiveness of our sampling strategy. The work of Felix et al. (2013) addressed some of the same issues and we found and reported similar results for the range of δ¹⁵N–NH₃ values (−56.1 to −2.2‰) from major NH₃ emission sources (including livestock, marine, vehicle, and fertilizer sources) as those presented here. These two independent studies determining the δ¹⁵N values of major NH₃ sources arrive at the same conclusion: NH₃ emitted from volatilized sources has relatively low δ¹⁵N values, allowing them to be distinctly differentiated from NH₃ emitted from traffic sources that are characterized by relatively high δ¹⁵N values.

Road tunnels are excellent locations to provide emissions from a large number of vehicles mixed with SCRs and TWCs under “real-world conditions” (T. Liu et al., 2014). Here we assume that the δ¹⁵N–NH3 values collected from a heavily used tunnel like the Handan tunnel (around 120,000 vehicles passing per day; an average of 65.9 µg m⁻³ NH₃ or 12.4 times the levels of open environment (Chang et al., 2016) can be accepted as the isotopic signatures of vehicles in China. Nevertheless, we note the δ¹⁵N–NH₃ values of vehicle exhausts that we collected from the Handan tunnel (−17.8 to −9.6‰; n = 8) are lower than the δ¹⁵N–NH₃ values determined by Felix et al. (2013) in the Squirrel Hill Tunnel, Pittsburgh (−4.6 and −2.2‰; n = 2). This Sino–US difference may be partially attributed to a higher usage of TWCs in the traffic in the USA.

The δ¹⁵N values of NH₃ from livestock (−31.7 to −27.1‰) and fertilizer (−52.0 to −47.6‰) that we measured are slightly lower than the range of δ¹⁵N–NH₃ values collected monthly from two dairy barns (−28.5 to −22.8‰) and a cornfield treated with urea–ammonia–nitrate fertilizer (−48.0 to −36.3‰) by Felix et al. (2013). These ranges of δ¹⁵N values are a function of the initial δ¹⁵N values of animal waste and fertilizer and variations in the bacteria populations, as well as other factors (temperature, wind, pH, etc.) that influence kinetic fractionation rates associated with NH₃ volatilization. Long-term (30 days) monitoring of δ¹⁵N and NH₃ emissions of manure measured by Lee et al. (2011) indicated that the dynamics of N isotope fractionation may be complicating the usefulness of the isotope approach as a tool for estimating NH₃ emissions in field conditions. In this sense, the shorter sampling period in our work should reflect the essence of δ¹⁵N values of livestock- and fertilizer-derived NH₃.

As a normal metabolic process, the release of NH₃ from human excreta has been well documented. However, most emission inventories involving human excreta have focused on pig latrines in rural areas of developing and middle income countries. In urban China, human excreta are typically stored in a three-grille septic tank under the building before disposal. After a series of anaerobic decomposition processes, a substantial amount of NH₃ will be generated and emitted through a ceiling duct. In the present study, the concentrations of NH₃ in the ceiling ducts (4509.3 ± 1248.0 µg m⁻³; n = 8) outweigh those in the open air by 3 orders of magnitude, and the δ¹⁵N–NH₃ values are seasonally consistent (−38.4 ± 0.9‰ in summer and −38.6 ± 1.0‰ in winter; Table 1), suggesting that human excreta may be an important and consistent source of NH₃ in urban areas. These data suggest that emissions of NH₃ from human excreta for an urban population of ~21 million people in Shanghai contribute 1386 Mg NH₃ annually to the atmosphere within the city, which corresponds to 11.4% of the total NH₃ emissions in the Shanghai urban areas (Chang et al., 2015). The δ¹⁵N values of wastewater-originated NH₃ (−41.0 ± 0.9‰; n = 8) are close to that of human excreta and also show no seasonal variation. Sampling in a stable and closed physical environment may be responsible for such a small range of isotopic variation. However, although also sampled in a closed environment, the δ¹⁵N values of municipal solid waste demonstrate a much greater variation (−37.6 to −29.9‰), which may be due to the variable composition of solid waste.

3.2 Source apportionment of ambient NH₃ in Beijing

Hourly observations of major air pollutants (including PM₂.₅, NOₓ, CO, SO₂, and O₃) in Beijing are show in Fig. S2. The meteorological differences (e.g., temperature and wind speed) for the three periods pre-, during and post-APEC are not significant, suggesting that emission reduction strategies implemented during the APEC summit were successful (Fig. S2). It should be noted that several control measures, i.e., closing factories within 200 km of the city center and stopping the entrance of out-of-city vehicles, had been undertaken in Beijing and its neighboring regions before the summit. Therefore, the before–during comparison of some pollutants like SO₂ are not in stark contrast in terms of their mass concentration (Fig. S2). The evolution of ambient NH₃ mass concentrations measured at CAU shows a similar pattern with CO and NOₓ (Fig. S3). Before the opening of the summit (from 18 October to 3 November), NH₃ concentrations averaged 9.9 µg m⁻³ and ranged from 6.9 to 11.0 µg m⁻³. During the summit session (from 3 to 15 November, the ending date of the summit is 13 November), this was reduced to

Atmos. Chem. Phys., 16, 11635–11647, 2016 www.atmos-chem-phys.net/16/11635/2016/

Y. Chang et al.: Source apportionment of atmospheric ammonia
7.3 µg m\(^{-3}\) with a range of 5.8–8.6 µg m\(^{-3}\). After the APEC summit (from 15 to 29 November), the NH\(_3\) concentration levels rebounded to an average of 12.7 µg m\(^{-3}\) (ranging from 10.7 to 17.7 µg m\(^{-3}\)). In other words, the NH\(_3\) concentrations were reduced by 20.0 % during the APEC summit compared with the period before it. Compared with the period after control, the concentrations were 74.5 % lower than that during the summit (Table 2).

On the basis of the δ\(^{15}\)N values of NH\(_3\) emission sources and ambient δ\(^{15}\)N–NH\(_3\) samples (Table 2), the ranges (within 5 and 95 percentiles) of relative contribution fractions of each NH\(_3\) source to the ambient atmosphere were modeled by the IsoSource and depicted in Fig. 3a–d. Of these, sources of traffic and fertilizer are better constrained than livestock and waste. This is because the δ\(^{15}\)N–NH\(_3\) values of the ambient atmosphere are closer to the latter two. For example, after the APEC summit in our study period, the δ\(^{15}\)N–NH\(_3\) values of the ambient atmosphere averaged −30.7 ‰, which is very close to the isotopic signature of livestock (−29.1 ‰), thus leading to weaker constraint with 5 and 95 percentiles ranges from near 0 to 0.7 (Fig. 3).

For each sample, information regarding the δ\(^{15}\)N value, the NH\(_3\) concentration and its source contributions is listed in Table 2. Figure 4 illustrates the overall source contribution proportions before, during, and after the summit, in which traffic, waste, livestock, and fertilizer comprised 20.4, 25.9, 24.0, and 29.7 % of the whole period (Table 2), respectively. Specifically, the contribution of traffic initially decreased by 56.7 % and then doubled, and this represents the largest change among the four sources (Table 2). Considering the absolute contributions of different sources to ambient NH\(_3\), these results show that traffic is the most sensitive source to the emission control measures. This result was expected since over half the vehicles in Beijing were banned from entering the city during the APEC summit (note that before the summit, out-of-city vehicles had already been banned from entering Beijing). Based on the vehicle NH\(_3\) emission factor obtained from real-world tunnel tests, T. Liu et al. (2014) and Chang et al. (2016) recently reported that vehicles contribute 8.1 and 12.0 % to total NH\(_3\) emissions in the Pearl River Delta region and Shanghai urban areas, respectively. With a total of 5.5 million vehicles in 2014, the traffic fleet in Beijing was much more than other cities. Thus, vehicle sources might contribute more than 20 % of the total NH\(_3\) to the air within Beijing.

The waste-originated percentages in Figs. 3 and 4 remain fairly constant over the sampling period, appearing to be a stable and important NH\(_3\) contributor in Beijing. Compared with wastewater and solid water, NH\(_3\) emissions from human excreta through in situ sceptic tank system are far from quantified. Based on an extensive measurement campaign, we estimated that the population of ~21 million people living in the urban areas of Shanghai annually emitted approximately 1386 Mg NH\(_3\), which corresponds to over 11.4 % of the total NH\(_3\) emissions in the urban areas (Chang et al., 2015). Non-agricultural sources – merged with waste and traffic NH\(_3\) emissions – collectively account for nearly 50 % of ambient NH\(_3\) before and after the APEC summit, which cannot be explained by previous work of emission inventories (e.g., Fu et al., 2013; Huang et al., 2011, 2012; Kang et al., 2016; M. Li et al., 2015; Zhang et al., 2009, 2010). Our results do not contradict a commonly held belief that agriculture is responsible for the vast majority (normally > 90 %) of total ammonia emissions at a regional scale. However, the results show that within urban areas, non-agricultural sources are very important. A consequence of the new results is that measures to im-

prove air quality in urban areas of China need to include measures to reduce both agricultural and non-agricultural sources of NH$_3$.

The NCP is one of the most intensive agricultural regions in China, enjoying a good reputation of “China’s granary” (Ju et al., 2009). Situated on the northern edge of the NCP with mountains to the north and west, Beijing is a receptor of agricultural NH$_3$ from rural areas. During our study period, crops in the NCP had been harvested and thus fertilizer application would have been very limited. However, our results show that fertilizer is the largest contributor, accounting for 29.7% throughout the sampling periods (Table 2). One explanation might be the prevalence of intensive urban agricultural production with high nitrogen fertilizer input in the suburban areas. Beijing’s increase in land area from 4822 km$^2$ in 1956 to 16808 km$^2$ in 1958 led to the increased adoption of periurban agriculture. Such “suburban agriculture” contributed $\sim$70% of non-staple food in Beijing, mainly consisting of vegetables and milk, to be produced by the city itself in the 1960s and 1970s (Cai, 2003). In the late 1990s, recognizing the importance of urban agriculture to sustainable urban development, Beijing’s municipal government launched an official program encouraging multi-function urban agriculture in peri-urban areas by supporting the development of “agro-parks”, which not only produce food but also attract tourism and are used as educational tools (Cai, 2003). One of the recent experiments in urban agriculture is the Modern Agricultural Science Demonstration Park in Xiaotangshan Town, Changping District (Cai, 2003). Today, Beijing is leading the way in using smart-city technologies to make urban farming more sustainable. In addition to suburban agriculture, there are 17 golf courses with 2280 ha. greens in Beijing; some of them are located at the urban areas (Chang, 2014). The turf grass of golf course typically needs 200–400 kg N ha$^{-1}$ yr$^{-1}$ as N fertilizer to achieve high performance (Wong et al., 1998, 2002; Zhang, 2002), which should be considered as an overlooked NH$_3$ contributor in Beijing.

### 3.3 Limitations and outlook

The data set reported in this study represents, to the best of our knowledge, the first attempt to partition urban atmospheric NH$_3$ sources. Considering the current nascent stage of partitioning NH$_3$ sources using stable isotope approach, there are several unsolved problems that could potentially undermine the above-mentioned results. One of our fundamental assumptions in this study is that the measured NH$_3$ was directly from NH$_3$ emission sources. In other words, we treated the measured NH$_3$ as the mixture of primary NH$_3$ sources without “gas-aerosol conversion” fractionation. But in fact, NH$_3$ $\leftrightarrow$ NH$_4^+$ equilibrium will cause $^{14}$N to be preferentially associated with NH$_3$ and $^{15}$N to be enriched in NH$_4^+$ of PM due to the stronger associative strength of $^{15}$N than $^{14}$N in NH$_4^+$ (Kawashima and Kurahashi, 2011; Yeatman et al., 2001). In Beijing, earlier studies confirmed that the atmosphere in Beijing was NH$_3$-limited, suggesting that acidic gases could not be fully neutralized to form ammonium salts (Ianniello et al., 2010; Wang et al., 2016). Therefore, ammonium salts had much less opportunity to volatilize to NH$_3$ to exert substantial isotopic effect through NH$_3$ $\leftrightarrow$ NH$_4^+$ equilibrium. Still, it is critical to develop a controlled laboratory system to fundamentally understand the characteristics and mechanisms of N isotope fractionations during the process of NH$_3$ transformation (Li et al., 2012).

Several additional factors could introduce uncertainty in the solutions of isotope mixing model. Given the complexity of urban NH$_3$ sources, no definitive solution exists in a linear mixing model with one isotope system tracer ($\delta^{15}$N) in the current study. Recommended future studies should include the combinations of different types of isotope ratio measurements and the adoption of more sophisticated Bayesian mixing models. The isotopic signature of sources like on-road traffic still remains uncertain. Some may argue that since NH$_3$ (also NO$_2$) is known to be a component of vehicle-emitted exhaust, why not collect vehicle-emitted NH$_3$ directly from the tailpipes. To our knowledge the $\delta^{15}$N of vehicle-emitted NH$_3$ has not been previously assessed. The tunnel test has a unique advantage in measuring the overall isotopic signatures of vehicle-emitted pollutants. We believe that the $\delta^{15}$N–NH$_3$ values of the samples collected from Handan tunnel in this study are representative as the isotopic signatures of vehicles in China.

Despite the potential limitations in this study, given the importance of NH$_3$ to PM$_{2.5}$ formation, this work can be expected to enrich the discussion on the methodologies (including stable isotope analysis) in terms of identifying the largest NH$_3$ sources in urban atmosphere where policy efforts relating to emissions abatement can be directed to deliver the largest impact.

### 4 Conclusions

First, we establish a pool of isotopic signatures ($\delta^{15}$N–NH$_3$) for the major NH$_3$ emission sources in China. The $\delta^{15}$N–NH$_3$ source inventory confirms that NH$_3$ emitted from on-road traffic has much higher $\delta^{15}$N values ($-14.2 \pm 2.8\%$), allowing them to be differentiated from other sources, such as livestock ($-29.1 \pm 1.7\%$), waste ($-37.8 \pm 3.6\%$), and fertilizer ($-50.0 \pm 1.8\%$).

Second, we demonstrated that the isotopic source signatures of NH$_3$ represent an emerging tool for partitioning NH$_3$ sources. Taking advantage of the implementation of stringent air quality control measures during the APEC summit in Beijing, the IsoSource modeling results indicate that the overall contribution of traffic, waste, livestock, and fertilizer to ambient NH$_3$ mass concentrations is 20.4, 25.9, 24.0, and 29.7%, respectively, in which traffic is the most sensitive to control measures. Our results clearly show that non-agricultural sources (traffic and waste) of NH$_3$ are of critical importance.
in megacities like Beijing. Therefore, in addition to current SO₂ and NO₃ controls, China also needs to allocate more scientific, technical, and legal resources on controlling non-agricultural NH₃ emissions in the future.

5 Data availability

All data in this paper are available in the Supplement.

The Supplement related to this article is available online at doi:10.5194/acp-16-11635-2016-supplement.

Acknowledgements. This work would have been impossible without the thought-provoking discussions with Yunting Fang at the Institute of Applied Ecology (IAE), Chinese Academy of Sciences. We sincerely thank Ying Tu at IAE, Yue’e Yang and Zi Li at the Shanghai Institutes of Life Sciences, for their assistance with the isotopic analysis. We also acknowledge the Qingyue Open Environmental Data Centre (http://data.epmap.org) for the unconditional help in terms of providing criteria pollutants monitoring data. Yunhua Chang acknowledges the support of the Gao Tingyao Scholarship and the start-up grant for outstanding young scholars by NUIST. This work was partially funded by the National Natural Science Foundation of China (Grant nos. 21377029, 21277030, 40425007, and 31421092) and the State Basic Research Program (2014CB954200).
