Abstract. The rate and direction of rift propagation through ice shelves depend on both the stress field and the heterogeneity (or otherwise) of the physical properties of the ice. The Brunt Ice Shelf in Antarctica has recently developed new rifts, which are being actively monitored as they lengthen and interact with the internal structure of the ice shelf. Here we present the results of a ground-penetrating radar survey of the Brunt Ice Shelf aimed at understanding variations in the internal structure. We find that there are flow bands composed mostly of thick (ca. 250 m) meteoric ice interspersed with thinner (ca. 150 m) sections of ice shelf that have a large proportion of sea ice and seawater-saturated firn. Therefore the ice shelf is, in essence, a series of ice tongues cemented together with ice mélange. The changes in structure are related both to the thickness and flow speed of ice at the grounding line and to subsequent processes of firn accumulation and brine infiltration as the ice shelf flows towards the calving front. It is shown that rifts propagating through the Brunt Ice Shelf preferentially skirt the edges of blocks of meteoric ice and slow their rate of propagation when forced by the stress field to break through them, in contrast to the situation on other ice shelves where rift propagation speeds up in meteoric ice.

the area lost (De Rydt et al., 2015; Hulbe et al., 2008; Rignot et al., 2004; Rott et al., 2011; Scambos et al., 2004; Shuman et al., 2011). These events have led to considerable current interest in the mechanisms of ice shelf fracture and break-up and the associated consequences for the far-reaching upstream impacts of such changes (Reese et al., 2018). Work on several ice shelves has demonstrated an association between internal structure and the rate and direction of rift propagation. On the Ronne Ice Shelf, Hulbe et al. (2010) noted that crack tips coincided with suture zones between ice originating from adjacent outlet glaciers through most of the advective path, with rifts propagating through the suture zones only near the ice front. On Amery Ice Shelf, Walker et al. (2015) showed rifts changing their propagation direction several times on entering the suture zone between two ice streams. A number of studies have focussed on the Larsen C Ice Shelf since the break-up of its northern neighbour (Glasser et al., 2009; Jansen et al., 2013; Kulesa et al., 2014; McGrath et al., 2012). Here, the details of the formation of suture zones with a high proportion of marine ice in areas immediately downstream of coastal promontories have been documented (Holland et al., 2009; Jansen et al., 2013). The suture zones are composed of accreted marine ice, sea ice, fallen meteoric blocks and accumulated snow from both drift snow captured in the surface depression and direct snowfall (Jansen et al., 2013; Leonard et al., 2008; McGrath et al., 2014). Numerous rifts in the meteoric ice bands terminate against the suture zones, indicating that the heterogeneous ice within the zones has higher fracture toughness, providing resistance to rift propagation through the ice shelf (Borstad et al., 2017). When the large rift in Larsen C Ice Shelf broke through the suture zone, the speed of propagation increased

1 Introduction

Ice shelves provide an important buttressing mechanism that restrains the ice flow from ice sheet interiors towards the ocean. The disintegration of the Larsen A and B ice shelves on the east coast of the Antarctic Peninsula resulted in substantial acceleration of the glaciers that formerly flowed into

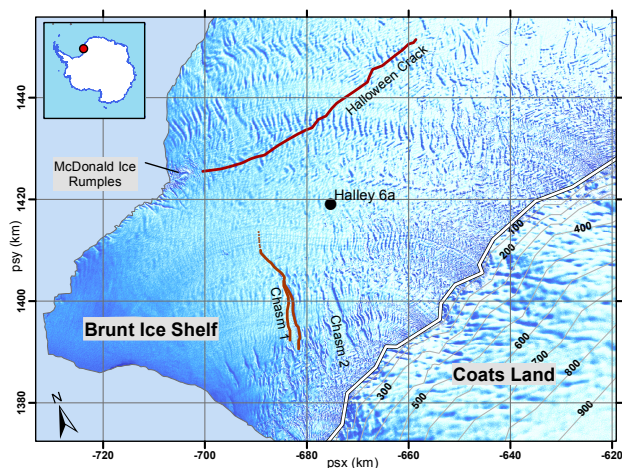

Figure 1. The Brunt Ice Shelf lies off Coats Land on the east side of the Weddell Sea, Antarctica (inset). The surface of the East Antarctic Ice Sheet slopes steeply down to the grounding line marked by a white line; elevation contours are at 100 m intervals. The ice shelf is partially grounded at the McDonald Ice Rumples. After several decades of sustained ice shelf growth, two rifts have developed in the past 2 years, marked by red lines. The first was an extension of a dormant rift known locally as Chasm 1; the second appeared on 31 October 2016 and is known as Halloween Crack. Halley Research Station was re-located to the position marked “Halley 6a” in January 2017. Projection is Antarctic Polar Stereographic (WGS84, EPSG: 3031).

markedly as the rift traversed meteoric ice. Suture zones are thinner, warmer and more heterogeneous than the meteoric ice and may have differences in water content and crystal fabric, all of which likely vary spatially throughout the zone. Which combination of these factors is most important in determining fracture toughness is still unknown. These examples from various ice shelves show that it is important to understand the internal composition and structure of ice shelves as this may impact on the rate and path of fracture. However, direct observations of the control exerted by internal structure on crack propagation are limited. Here we present for the first time direct evidence that the path of propagation is directly influenced by deep-lying structures within an Antarctic ice shelf.

1.1 Study area

The Brunt Ice Shelf is located on the eastern coast of the Weddell Sea (Fig. 1) and forms the southernmost portion of a complex ice shelf that incorporates the Stancomb-Wills Glacier Tongue and the Riiser-Larsen Ice Shelf to the east. The Brunt Ice Shelf flows northwest from the coast of Coats Land with a speed of $> 500 \text{ m a}^{-1}$ at the calving front, although there is strong temporal variability in the flow regime (Gudmundsson et al., 2017). The flow is restrained

by grounding at the McDonald Ice Rumples (Fig. 1) in the northeast corner of the ice shelf (Thomas, 1973a, b, 1979).

The grounding zone between the Brunt Ice Shelf and the grounded ice in Coats Land is steep and heavily crevassed, so that the entire ice sheet breaks up into large blocks between 2500 and 6000 m long and 250 to 900 m wide. Therefore, the majority of the ice shelf within 15 to 20 km of the grounding line actually comprises icebergs surrounded by sea ice and has large topographic relief (Fig. 2). Accumulation of falling and drifted snow infills the topography such that the surface of the downstream part of the Brunt Ice Shelf undulates gently, giving little indication of the underlying structure. The presence of marine ice deposited at the base of the ice shelf is highly likely (Khazendar and Jenkins 2003; Khazendar et al., 2009).

In this study, we use ice-penetrating radar surveys to describe aspects of the internal structure of the Brunt Ice Shelf and interpret potential mechanisms for its development. Previous studies of the ice shelf using radio-echo sounding (Bailey and Evans, 1968; Walford, 1968) showed that echo strength from the base of the ice was highly variable and that there were regions of very high attenuation where no basal echoes were recorded. The high attenuation was attributed to the percolation of seawater or the presence of saline ice formed from seawater. We have applied up-to-date radar sounding equipment and techniques to provide better spatial coverage and resolution than the previous efforts.

An extensive network of GPS monitoring stations has been established on the Brunt Ice Shelf as part of the infrastructure for Halley VI Research Station (Anderson et al., 2014). Recently, two significant new rifts developed in the ice shelf (De Rydt et al., 2018), one an extension of “Chasm 1” (Fig. 1), which has remained unchanged since the 1970s; one a new rift named “Halloween Crack” (from the date of formation on 31 October 2016). Thus the region around Halley Research Station is a unique place to study the impact of ice shelf structural heterogeneity on fracture propagation because dynamic changes are underway within a well-monitored environment and the station provides a logistic hub to undertake extensive ground-penetrating radar survey. The rate and direction of propagation of Halloween Crack changed when the crack tip entered a region of thicker ice shelf thought to comprise closely spaced blocks of meteoric ice (De Rydt et al., 2017). In this paper, we use radar results to determine the degree of heterogeneity in ice shelf internal structures and discuss how this came to be.

In Sect. 2 the regional surface and basal topographic data are reviewed. In Sect. 3 the radar data acquisition and processing is described. Section 4 describes and interprets the radar profiles. In Sect. 5, we will discuss the radar profiling results in terms of the internal structure of the ice shelf, and the implications for fracture propagation are presented in Sect. 6.

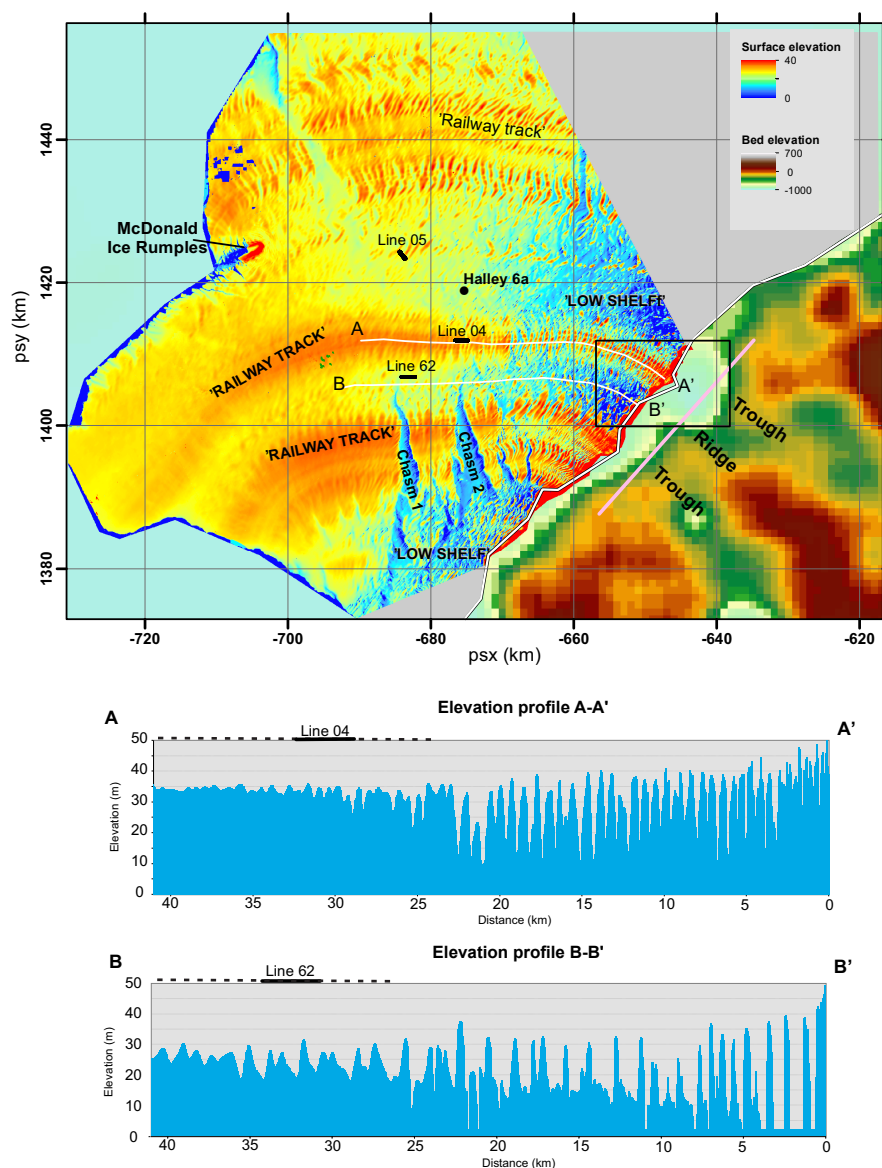

Figure 2. Surface elevation of the Brunt Ice Shelf and the bedrock elevation beneath grounded ice in Coats Land. Flow lines downstream from troughs in the bedrock have higher elevation throughout the ice shelf (orange colours). Near to the grounding line these elevated bands comprise closely spaced ridges resembling railway sleepers; hence we term the bands “railway tracks” for descriptive purposes. White lines show locations of elevation profiles extracted from the digital elevation model and shown below the map. Line locations in continuous black mark sections of radar profiles shown in Figs. 4 and 5 (dashed black lines over profiles show full extent of profiles). Pink line is location of flow speed profile shown in Fig. 3. Box is the extent of the satellite image shown in Fig. 6.

2 Observations

2.1 Surface topography

The surface topography (Fig. 2) is based on a number of 3 m resolution WorldView digital elevation map tiles acquired between 2012 and 2014. To stitch tiles together, one tile, which included the buildings of Halley VI Research Station, was designated the anchor tile, and adjacent tiles were shifted manually in x , y and z coordinates (without rotation) to

match identifiable points between pairs, particularly in near-static areas around the McDonald Ice Rumples and on the grounded ice sheet. There are several distinctive topographic regions as follows.

- An inner region within 20 km of the grounding line. Here there are large areas where the snow surface is between 1 and 10 m above sea level (blue colours in Fig. 2).

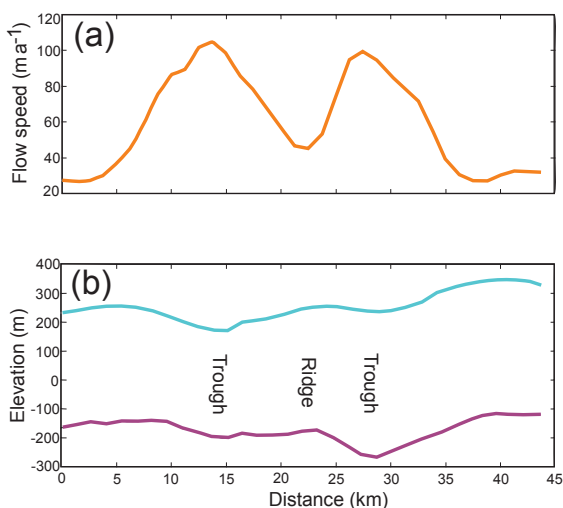

Figure 3. (a) Flow speed profile across a gateway 5 km upstream of the grounding line (marked in Fig. 2). (b) Surface and bed elevations for the gateway.

- Curvilinear bands where the average elevation is 35 m above sea level (orange colours in Fig. 2). These bands can be traced from the grounding line to the calving front. They have a distinctive appearance created by undulations which is reminiscent of close-spaced railway sleepers. For the purposes of description, we term them “railway tracks”. The spacing of the “sleepers” is around 1.5 km (profile A–A', Fig. 2).
- Intervening bands where the average elevation of the ice shelf is low; in particular in the first 20 km from the grounding line large areas are within 2 m of sea level with scattered highs rising to 35–40 m. With distance from the grounding line, the broad troughs become filled in, while the peaks decline in elevation from 35–40 to 25–30 m (profile B–B', Fig. 2). High points in these bands are more widely spaced and irregular than in the “railway tracks”.
- Steep-sided, flat-bottomed rifts with walls around 30 m high. These are locally known as chasms (Chasm 1 and Chasm 2, Fig. 2). The chasms extend 30 km into the ice shelf from the south.

2.2 Subglacial topography

The Bedmap2 database (Fretwell et al., 2013) was used to map the subglacial topography beneath the grounded ice in Coats Land (Fig. 2). Within the mapped area there are two 10 km wide troughs with an intervening ridge that are oriented approximately orthogonal to the grounding line. Ice flow speed derived from interferometric synthetic aperture radar (InSAR) data (Rignot et al., 2017) shows that within the troughs flow speed peaks at 105 and 100 m a⁻¹, whereas

ice flowing off the ridges has a flow speed of between 15 and 35 m a⁻¹ (Fig. 3).

3 Radar acquisition and processing

The data were collected between December 2015 and February 2016 using a commercial ground-penetrating radar system (Sensors and Software pulseEKKO PRO) operating at a centre frequency of 50 MHz. The system was mounted on a sledge, which was towed behind a snow mobile travelling at 15 km h⁻¹, with traces recorded continuously. Positioning information was recorded using a dual-frequency GPS receiver, and the satellite range information was processed through the Canadian Geodetic Service Precise Point Positioning service in kinematic mode. This methodology provided radar profiles with positions accurate to around 0.5 m. The radar data were processed using ReflexW software by applying a bandpass filter (with corner frequencies 10/20/60/120 MHz), a spherical spreading correction, a horizontal filter to remove the direct arrival, and time migration. A fixed wave speed of 0.168 m ns⁻¹ was used for both migration and depth conversion because the construction of a detailed wave speed model for the ice shelf using multiple common mid-point determinations was beyond the scope of the survey. We therefore elected to use the fresh water ice wave speed of 0.168 m ns⁻¹ throughout. We estimate that our figures for the thickness of the ice shelf where most of that thickness is made up of meteoric ice have an uncertainty of about 20 %. Where there is significant thickness of pure firn (i.e. not infiltrated with seawater), the use of a uniform wave speed underestimates the overall ice shelf thickness by approximately 5 %.

4 Radar data

4.1 Data description

In this section, we will first describe the reflection character of some example radar profiles taken from a large data set. We will then interpret the different reflection facies observed in terms of their glaciological origins.

Portions of two flow-line radar profiles 1800 m long are presented in Fig. 4. The locations are shown in Fig. 2. Line 04 was acquired in one of the “railway track” bands of slightly higher topography. Line 62 was acquired in the adjacent lower-topography region to the west of Line 04.

Line 04 (Fig. 4a, b) has a near-surface radar facies of undulating, layered, continuous reflections between 13 and 60 m thick. This facies is colour-coded yellow in the figures. The layered facies lies above a second facies with irregular scattered reflections of highly variable amplitude (colour-coded blue). The deepest sections of the interface between the two facies are characterized by very high amplitude laterally continuous reflections (orange). The remainder of the profile is

largely reflection-free until a band of curvilinear reflections at between 240 and 270 m below surface. The events marked as multiples are reflections that arise from internal reverberation between strong reflectors.

Line 62 (Fig. 4c, d) also has an upper radar facies of undulating, layered, continuous reflections, this time between 13 and 40 m thick. There are three regions with irregular scattered reflections of variable amplitude forming prominent highs in the section. Between these highs there is a near-horizontal reflection with very high amplitude at approximately 40 m below surface (the surface is at 22 m above sea level). This reflection has a prominent multiple. Below the three highs, there are weak scattered reflections and then, at around 150 m depth, a set of high-amplitude curvilinear reflections.

Figure 5 shows another example and more detailed view of the radar reflection facies described above. Line 05 (for location see Fig. 2) is located in one of the lower-topography bands in the ice shelf but adjacent to some isolated ridges. The upper radar facies of undulating, layered, continuous reflections is between 21 and 50 m thick. The second facies of irregular scattered reflections of variable amplitude forms a single high between 450 and 680 m along the profile. Elsewhere, the base of the layered facies is a very high amplitude reflection which is conformable to the layers above in some places and is flat-lying between 170 and 330 m along the profile.

4.2 Interpretation

The undulating, layered, continuous reflection facies is interpreted as firn deposited in situ on the ice shelf. The reflections are isochrones; therefore the spacing between them gives an indication of the local relative accumulation rate (e.g. Vaughan et al., 2004, 1999). The radar system does not have sufficient vertical resolution to image individual annual layers; the reflections observed are the result of the convolution of returns from many, more finely spaced, reflectors.

The radar facies with irregular scattered reflections of variable amplitude is interpreted as the returns from blocks of meteoric ice embedded in the ice shelf (this facies is coloured blue in Figs. 4 and 5). Figure 6 shows a visual satellite image of the region around the grounding line (the location is shown as a black rectangle in Fig. 2). It is evident that the ice flowing over the grounding line is completely riven by crevassing and that the ice shelf at this point comprises more or less closely packed icebergs held together by sea ice (Fig. 6b). The curvilinear reflections at depth on lines 04 and 62 (Fig. 4) are interpreted as arising from the ice–water interface at the base of the embedded icebergs. The undulations of the firn reflections in the upper radar facies (yellow colouring) indicate differential accumulation between and over the embedded icebergs (Figs. 4 and 5). It is also possible that undulations in the firn may, in part, be due to horizontal shortening induced by

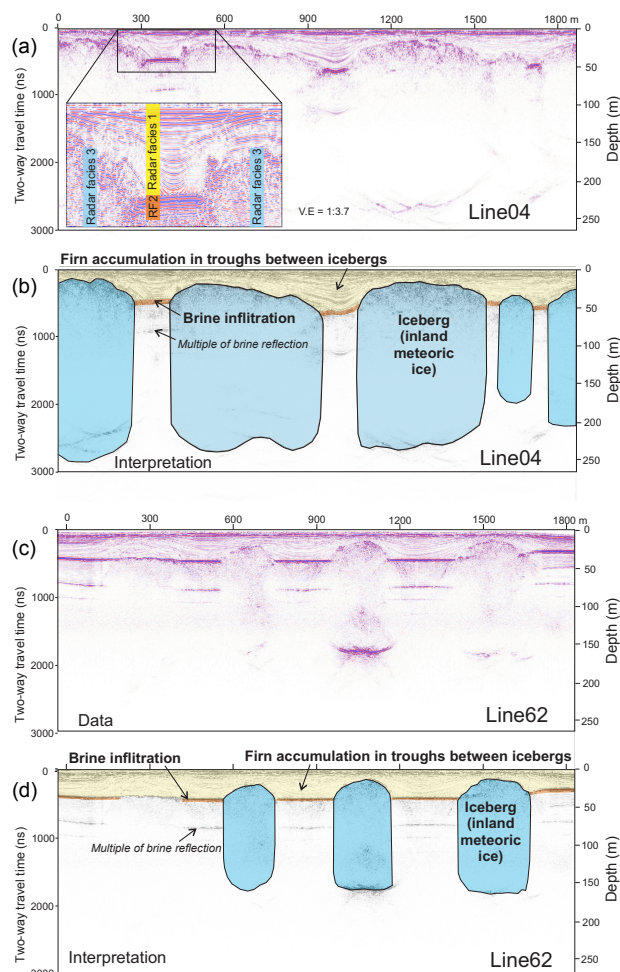

Figure 4. Ice shelf cross sections acquired with a 50 MHz ground-penetrating radar system. Locations are marked in Fig. 2. Radar facies descriptions and interpretations are given in the text. **(a)** Line 04 lies along one of the “railway tracks”. Three radar facies are identified (inset). **(b)** Interpretation of line 04. Radar facies 1 is interpreted as firn accumulated by snow fall and drift on the ice shelf. Radar facies 2 is interpreted as a brine horizon. Radar facies 3 is interpreted as blocks of meteoric ice that originate as icebergs calved off the inland ice sheet at the grounding line; the blocks are up to 200 m thick. **(c, d)** Radar cross section from line 62 in the thinner ice shelf area between two of the “railway tracks”. The icebergs are significantly thinner and more widely spaced.

historic changes in flow speed of the ice shelf (Gudmundsson et al., 2017).

The very high amplitude reflection (orange colour in figures) that is near-horizontal in Fig. 4c and in parts cross-cutting and parts conformable with the firn layering in Fig. 5 is interpreted as a brine infiltration front. The reflection cross-cuts the isochronal reflections, suggesting a later, non-stratigraphic origin. There is strong attenuation beneath the reflector which, together with the very high amplitude, suggests a large contrast in electrical conductivity. Liquid brine

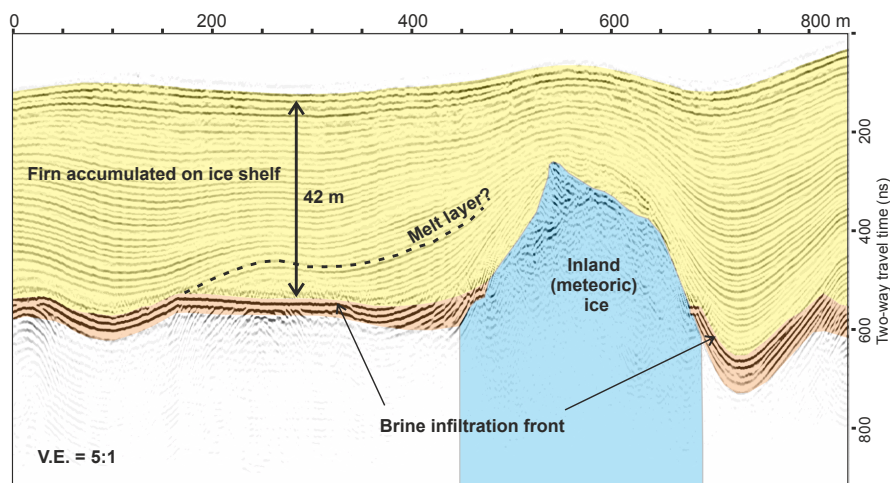

Figure 5. Close-up of a section of radar profile (line 05, location in Fig. 2) that illustrates different structure on the brine reflection. In some places the reflection is horizontal and cross-cuts reflections in the firn layer. Elsewhere the reflection is conformable with the isochronal reflections in the firn layer.

was found in a hole drilled in the “thin ice shelf” to the west of the MacDonald Ice Rumples (Thomas, 1973b). The brine was found at a depth of 1.5 m below sea level. Its temperature was -10°C , suggesting a salinity of 125‰. Immediately below the brine was bubbly impermeable ice. Brine infiltration has been observed on radar profiles of the McMurdo Ice Shelf (Grima et al., 2016; Kovacs and Gow, 1975; Morse and Waddington, 1994) as well as the Wordie Ice Shelf, the Larsen Ice Shelf and Wilkins Sound (Smith and Evans, 1972).

The brine reflection observed in Figs. 4 and 5 is considerably deeper than sea level at those locations. Figure 7 shows an example of a radar profile that approaches one of the large rifts in the ice shelf. On this profile there are very high amplitude near-horizontal reflections at two levels. The upper level is close to sea level, while the other is 13 m lower. We interpret this profile as indicating that there has been recent brine infiltration horizontally from the rift where seawater can be observed in cracks in the sea ice flooring the chasm. We suggest that the other reflection arises from an older brine infiltration event, which may have a different mechanism, which will be discussed in the next section.

5 Discussion

We have established that the “railway track” bands of higher elevation originated at the grounding line in locations where there are troughs in the bed topography. Conversely the bands of lower topography originated at ridges in the bed topography beneath Coats Land. Figure 8 summarizes the situation in cross section. Ice flowed from the troughs in bedrock at a higher rate than off the ridges, providing a steady stream of large, thick blocks of meteoric ice that formed a closely

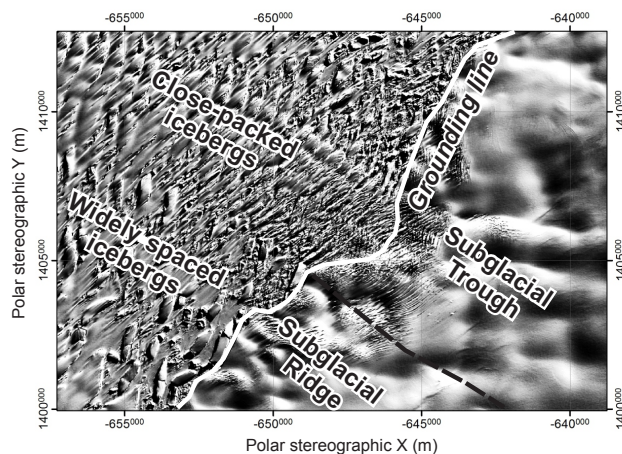

Figure 6. Landsat image of the region around the grounding line (location Fig. 2). Intense crevassing occurs 3–4 km upstream of the grounding line; the ice retains no structural integrity on crossing the grounding line; the ice shelf is composed entirely of separated blocks held together by sea ice. Where the ice flows from a subglacial trough, the blocks remain closely packed with narrow channels of sea ice between them, but where the ice flows off a subglacial ridge, the blocks are widely spaced with extensive areas of sea ice between.

packed flow band within the ice shelf. Ice that flowed off the ridges in the bed topography was thinner and supplied to the ice shelf at a slower rate. As a result, the meteoric ice blocks were both thinner and more spaced out, resulting in isolated icebergs surrounded by large areas of sea ice (Fig. 2, topographic profile B–B'; Figs. 3c, 6b).

The majority of Antarctic ice shelves are formed by the coalescence of glaciers or ice streams that flow across the

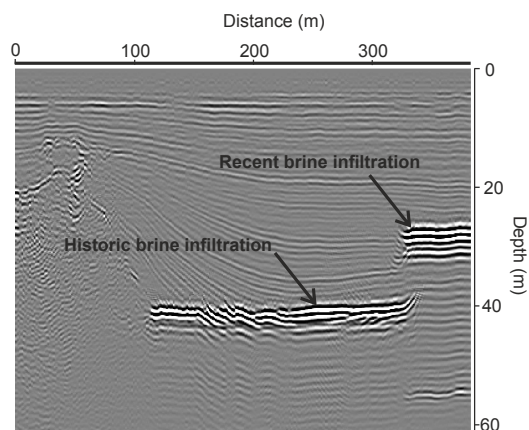

Figure 7. Westernmost section of radar profile from line 62 (Fig. 2) near Chasm 1. High-amplitude reflections interpreted as brine infiltration horizons are observed at 26 and 39 m below the surface of the ice shelf. The depth of the upper reflection coincides with sea level in the adjacent rift, suggesting horizontal migration of seawater through porous and permeable firn recently exposed to the ocean. The lower reflection is interpreted as seawater infiltration that became frozen in place some distance upstream.

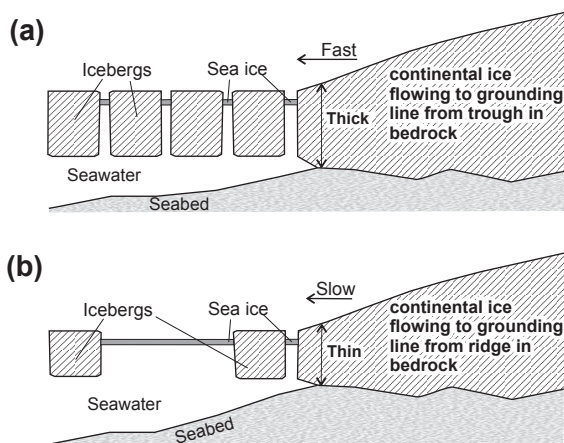

Figure 8. Illustration of the origin of the two different structures within the Brunt Ice Shelf. (a) Ice flowing out of a subglacial trough at around 100 m a^{-1} breaks up into closely packed icebergs separated by narrow channels in which sea ice forms. (b) Where thinner ice flows over the grounding line at a slower rate, the supply of ice is insufficient to match the flow speed of the ice shelf (which is driven by the faster ice coming out of the troughs), so the structure comprises thin, widely spaced icebergs separated by wide expanses of sea ice.

grounding line in structurally coherent bodies, perhaps with some surface or bottom crevassing, but otherwise intact. The Brunt Ice Shelf is one of a class of ice shelves (other examples are Thwaites Glacier Tongue, the western sector of Cook Ice Shelf and the ice shelf lying off the Leopold and Astrid Coast) comprising ice which retains no structural in-

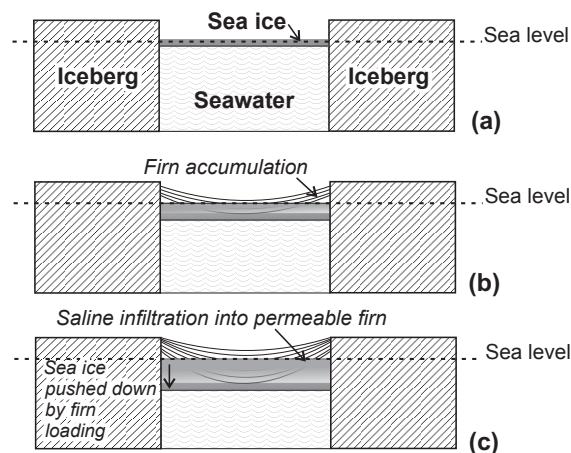

Figure 9. Illustration of the process by which sea ice between icebergs becomes loaded by firn accumulation and is driven below sea level by hydrostatic adjustment, allowing seawater to soak into the porous and permeable firn from below.

tegrity when flowing across the grounding line; as a result, the blocks of meteoric ice are cemented together by sea ice and drift snow to form the ice shelf.

The process which cements together the ice shelf involves the gaps between meteoric ice blocks being filled first by sea ice and then by drift snow which consolidates into firn (Fig. 9a and b). The isostatic loading by snow accumulation pushes the sea ice downwards until it lies below sea level. At this point, the process of firn consolidation has not advanced to pore close-off and the firn is still porous and permeable, allowing seawater to soak the firn. Freezing cycles then concentrate the salt to leave a brine horizon (Fig. 9c). In Fig. 5 the topography on the high-amplitude reflector provides evidence that the brine infiltration may have occurred by sinking of the firn rather than by horizontal spreading of salty water. Warm periods in the summer can produce melt horizons within the firn, creating an impermeable layer. Our hypothesis is that the soaking of the firn from below as it sank to ocean level may have been blocked by the impermeable layer in the region between 50 and 150 m along line 05 (Fig. 5). This would explain why the brine infiltration reflector is a syncline conformable with the firn layering in this section of the profile. The same process may have occurred between 670 and 800 m along the profile, although it is also possible that enhanced accumulation in this region created or deepened the syncline there after the brine horizon had frozen in place. Another possible explanation of the syncline in the brine reflector between 670 and 800 m is horizontal shortening induced by variations in the flow speed of the ice shelf.

It is not clear what controls the termination of the process of brine infiltration and locks the high-amplitude reflector in place within the ice shelf so that it descends below sea level as further accumulation takes place. It is likely that a balance

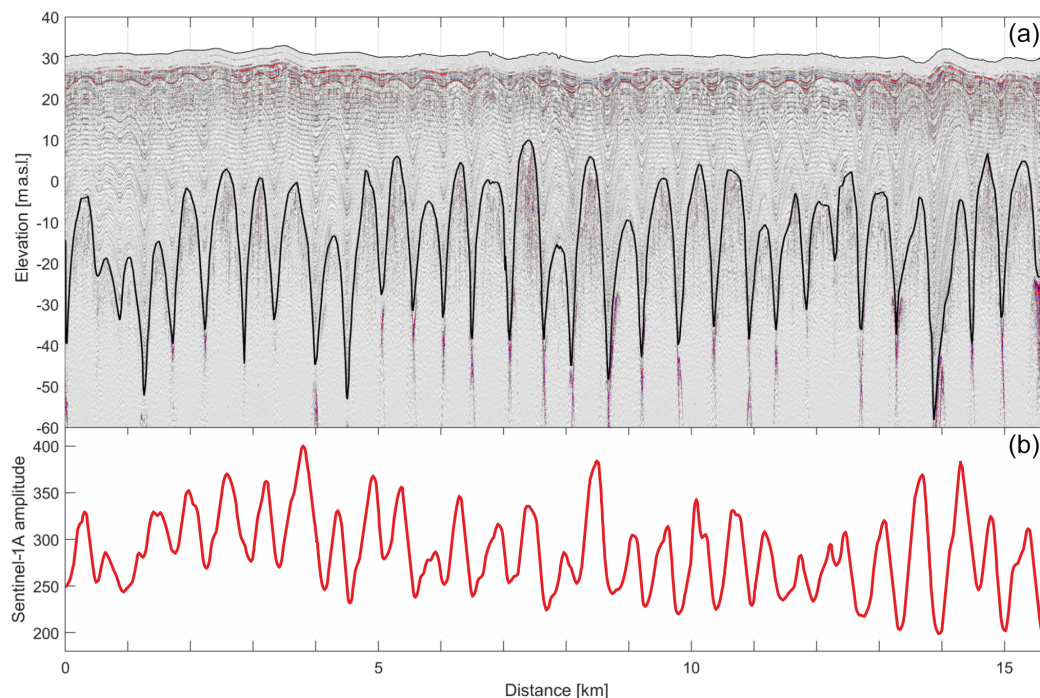

Figure 10. (a) The upper 90 m of a radargram along the “railway track” near Halley VI Research Station compared to (b) the Sentinel-1 backscatter amplitude along the same line.

between pore space reduction by compaction of the firn and freezing of seawater in the gaps between ice crystals eventually reduces the permeability of the firn to nothing at a depth shallower than the dry firn pore close-off would be. Another factor may be the formation of marine ice below these sections of developing ice shelf in a similar fashion to the formation of marine ice in rifts described by Khazendar and Jenkins (2003). While marine ice is porous and permeable when first formed, it thickens and consolidates over time and could eventually close off access for seawater to the lower sections of firn.

The lower-elevation bands between the “railway tracks” in the Brunt Ice Shelf have many of the characteristics of ice mélange; that is, they combine sea ice, marine ice, firn and scattered meteoric ice blocks. Ice mélange has been identified as a prominent feature of the Brunt Ice Shelf–Stancomb-Wills Ice Tongue system (Khazendar et al., 2009), where large areas were identified on either side of the Stancomb-Wills Ice Tongue cementing together large tabular icebergs. Thought of in this way, the Brunt Ice Shelf is a series of ice tongues cemented together by ice mélange to create a single mass with highly heterogeneous properties.

This heterogeneity of structure has a number of potential implications. For example, the icebergs of meteoric ice may have a different bulk density compared to the adjacent mixture of firn, sea ice and marine ice in the mélange. If the bulk density were significantly different, it would affect the thickness-from-freeboard calculations that are carried out

over ice shelves where there are no ground-truth thickness measurements (Griggs and Bamber, 2011). Khazendar et al. (2009) estimated the temperature of ice mélange at between -11 and -7°C and that of meteoric ice at between -21 and -15°C . This has implications for melt rate calculations, and the different types will produce meltwater of different salinity.

The propagation of a large rift through the Larsen C Ice Shelf was shown by Borstad et al. (2017) to be faster through meteoric ice than through suture zones, implying greater fracture toughness in the suture zones. It is not known whether the mechanical properties of the ice in suture zones constrained between large homogeneous bodies of meteoric ice such as those in the Larsen C Ice Shelf are similar to the mechanical properties of the ice mélange in the Brunt Ice Shelf. There are strong similarities in the way the material forms but post-formation history may be important in the development of the mechanical properties. For example suture zones can experience high shear strain (Jansen et al., 2013), whereas the ice mélange areas of the Brunt Ice Shelf probably do not.

6 Implications for fracture propagation

The heterogeneous structure of the ice shelf influences the rate and direction of the propagation of fractures. Over about half the area of the ice shelf, the location of the meteoric ice-

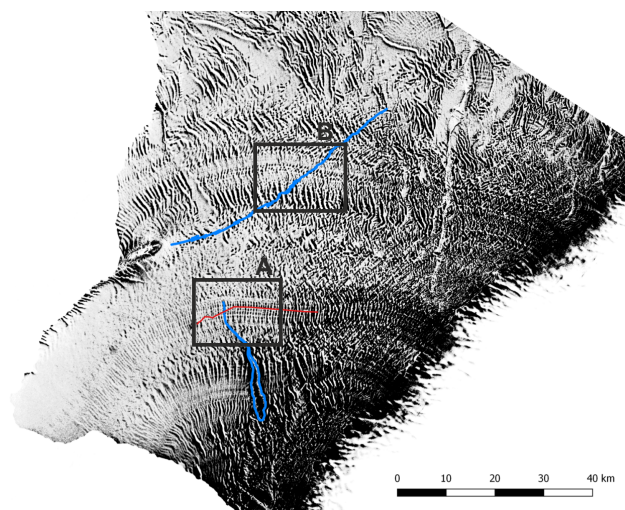

Figure 11. Map showing radar backscatter proxy for the presence of meteoric ice. Over most of the ice shelf, black indicates the presence of meteoric ice, and white areas correspond to infill by sea ice and firn. Boxes indicate the location of detailed views in Figs. 12 and 13. Red line is the location of the profile in Fig. 10.

bergs can be identified from the surface topography (Fig. 2). Where firn accumulation has buried the icebergs completely in the outer part of the ice shelf, the location of the meteoric ice can be mapped using SAR satellite imagery. The top panel in Fig. 10 shows a radargram of the upper 90 m of ice shelf in the central “railway track”, following the red line in Fig. 11 from its most western point towards the grounding line. The black line in Fig. 10 marks the interface between radar facies 1 (firn) and facies 2 and 3 (brine and meteoric ice). The bottom panel shows the backscatter amplitude along the same section from a Sentinel-1A radar image acquired on 29 October 2017. A Gaussian filter with a radius of 40 m was applied to suppress small-scale noise. There is a very high correlation ($r = 0.607$, $p = 0$) between peaks in the backscatter amplitude and the zones of thin firn overlying the crests of the icebergs. This correlation is not a coincidence, as the C-band sensor on Sentinel-1A is known to penetrate the surface of the ice (Bingham and Drinkwater, 2000), and it is therefore capable of picking up the spatial variability in the structure of the ice near the surface. However, the details of this mechanism remain subject to future study, and here we merely note its existence. Using radar backscatter from Sentinel-1A as a proxy, the spatial distribution of meteoric ice can be mapped across the entire ice shelf, as illustrated in Fig. 11.

The complete map of ice shelf heterogeneity provides a unique opportunity to interpret observed changes in the trajectory and propagation speed of two major rifts (Chasm 1 and Halloween Crack) in the ice shelf, and to relate these changes to the internal structure of the ice shelf. To highlight the different ways in which the rifts interact with the inter-

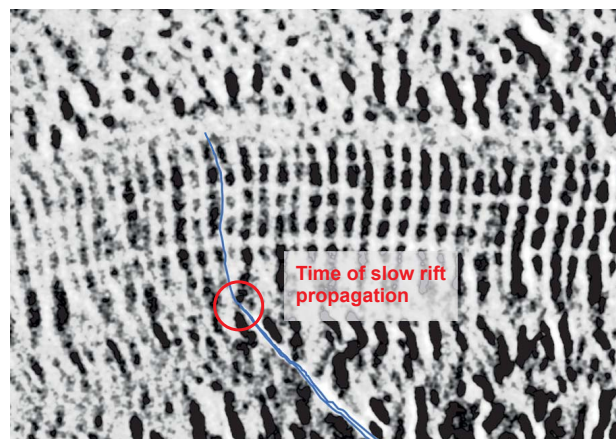

Figure 12. Detailed view of the tip of the Chasm 1 crack (blue curve). The background image distinguishes areas with meteoric ice (dark) from areas with sea ice overlain by firn. When the crack went through one of the blocks of meteoric ice rather than around it (red circle), the rate of propagation slowed.

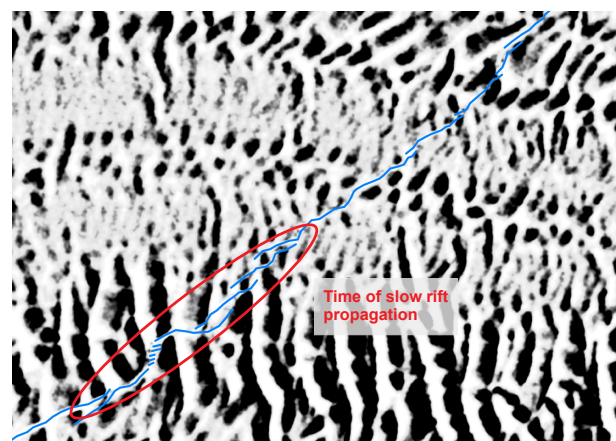

Figure 13. Detailed view of part of the Halloween Crack (blue curve). Crack propagation slowed when the crack crossed one of the “railway tracks” at a high angle to the meteoric ice blocks. Rift extension speed then increased in the ice mélange beyond.

nal structure, we focus on two small regions outlined by the black boxes (A and B) in Fig. 11. Region A (Fig. 11) covers the tip of Chasm 1 in November 2017; a detailed view is shown in Fig. 12. The overall direction of propagation of Chasm 1 is dictated by the large-scale stress field in the ice shelf, with a trajectory that is perpendicular to the direction of maximum tensile stress (De Rydt et al., 2017; Gudmundsson et al., 2017). However, Fig. 12 shows that at smaller length scales the exact trajectory is dictated by the location and shape of the meteoric icebergs, and Chasm 1 follows pre-existing lines of weakness along the edges of the icebergs, in particular within the “railway track”. Only at one instance did Chasm 1 propagate through an area of meteoric ice (red cir-

cle in Fig. 12), which coincided with a period of significantly slower propagation rates (De Rydt et al., 2017).

Region B (Fig. 11) covers part of the Halloween Crack where the rift propagated through the northern “railroad track”; a detailed view is shown in Fig. 13. The overall direction of propagation is again dictated by the stress distribution in the ice shelf, which forces the Halloween Crack to cross an area with a high concentration of meteoric ice, where the edges of the iceberg are misaligned with the overall direction of propagation (red ellipse in Fig. 13). This has resulted in a more complex propagation behaviour, where the rift followed edges of the icebergs for short periods and broke through the icebergs in places of weakness, such as discontinuities in the “railway sleepers”. For the remainder of the trajectory shown in Fig. 13, the rift, while generally following a path dictated by the stress field, in detail weaves its way around scattered icebergs within the ice shelf, avoiding fracturing through areas of meteoric ice. Thus, fracture through the Brunt Ice Shelf progresses at contrasting rates to rifts through other documented ice shelves. Elsewhere rift extension rates increase in meteoric ice and decrease in suture zones comprising ice mélange, whereas recent Brunt rifts slow in meteoric ice and speed through ice mélange. This suggests that there is a difference in the physical properties of ice that was formed in similar ways but which had different subsequent histories, e.g. amount of shear strain, during advection through the ice shelf.

7 Conclusions

Unusually the Brunt Ice Shelf is composed of alternating bands of ice of two types which have different origins and compositions. The first type is identifiable on visual satellite imagery by a “railway track” appearance and comprises large blocks of meteoric ice originating in the ice sheet in Coats Land which are cemented together by thin strips of sea ice and firn. This type is mostly thick freshwater ice. The second type has a random appearance on satellite images and comprises an ice mélange of relatively thin scattered blocks of meteoric ice from the continent separated by large areas of sea ice (probably underlain by marine ice) and firn that has been soaked by seawater and refrozen.

While a fracture propagating through the Larsen C Ice Shelf sped up when traversing through meteoric ice and slowed in suture zones, fractures observed in the Brunt Ice Shelf slowed when going through meteoric ice blocks and were often routed through the ice mélange in the gaps between the meteoric ice. This contrast in styles of fracture propagation in different ice shelves needs to be better understood so as to improve predictive modelling of ice shelf stability.

Data availability. The ground-penetrating radar data are available upon request from the authors. All data will be made available through the UK Polar Data Center (<http://www.bas.ac.uk/data/uk-pdc/>; BAS, 2018) once the project is complete. Sentinel data are available through the ESA Science Hub. The products are available through <https://scihub.copernicus.eu> (Serco, 2018). An 8 m resolution surface elevation DEM is now available through the REMA project at <https://www.pgc.umn.edu/projects/the-reference-elevation-model-of-antarctica-release-1> (PGC, 2018).

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. The authors are grateful for the support provided by the station personnel of Halley VI Research Station. This work was part of the British Antarctic Survey programme “Polar Science for Planet Earth” funded by the Natural Environment Research Council, UK. The authors thank Adam Booth, Daniel McGrath and an anonymous referee for their useful comments for improving the paper.
