ABSTRACT: Pb isotope analyses is an increasingly widespread tool in the study of environmental pollution as lead isotope compositions do not change during industrial and environmental processes, and always reflect their source origin. In this study we present the results of R-mode factor analysis for associations between chemical elements in Neapolitan soils, combined with the distribution of Pb concentrations and Pb isotope compositions in order to differentiate natural from anthropogenic metal sources. Results show Neapolitan urban soils to be significantly enriched in Pb, Hg, Zn, Sb, and to a lesser extent in Cu, Cd, Cr and Ni. Lead isotope measurements form a trend suggesting mixing between two end-member compositions, one of clear natural origin (geogenic) and another related to human activities (anthropogenic). Pb isotope investigations demonstrate that road traffic is one of the main sources of metal pollution.

KEYWORDS: Heavy metal, urban soil, environmental pollution, Pb isotopes, R-mode factor analysis.

INTRODUCTION

In recent years, many scientists have focused their interest on heavy metals in the soils of urban areas where pollution might have a direct influence on public health (Markus and McBratney, 2001; Fordyce *et al.*, 2005, Wong *et al.*, 2006). This is due to the frequent, close, juxtaposition of humans with soils either as suspended dust or by direct contact. Furthermore, the compilation of databases of trace metal concentrations have enabled informed decision making for setting soil protection guidelines and determining the suitability of a particular land use, by assessing potential risk to humans or the environment. Mapping contaminant distribution allows immediate appraisal of the variability of harmful elements in an area and enables rapid identification of areas that may contain excessive concentrations of toxic metals (Facchinelli *et al.*, 2001; Salminen *et al.*, 2005; Lee *et*

et al., 2006). This is essential for site and subsequent risk assessment (Manta *et al.*, 2002; Cicchella *et al.*, 2005; De Vivo *et al.*, 2006).

In the Napoli metropolitan area it has already been shown (Cicchella *et al.*, 2005) that heavy metal compositions of soil are affected by a combination of two components: one natural, related to volcanic lithologies; and one anthropogenic, related to traffic and industrial activities. In this study we present the factor score distribution of elemental associations resulting from R-mode factor analysis, along with the distribution of Pb concentrations and Pb isotope compositions in order to differentiate natural from anthropogenic sources.

In the last 50-100 years, the natural geochemical Pb cycle has been completely overwhelmed by anthropogenic emissions in the atmosphere from industrial and vehicle contamination (Nriagu, 1989; Pacyna and Pacyna, 2001; USGS, 2002). Pb isotope analyses are widely used to study environmental pollution as the lead isotope composition does not change during industrial and environmental processes, but always reflects the source origin. In addition, Pb is relatively immobile in the surface environment and it is ubiquitous in many industrial processes.

The introduction of Pb into soils occurs by atmospheric deposition and by incorporation of Pb from underlying bedrock. Stable Pb isotope ratios, in combination with concentration data of Pb and other heavy metals, are an useful method of differentiating natural from anthropogenic sources (Erel *et al.*, 1997; Hansmann & Köppel, 2000; De Vivo *et al.*, 2001a; Charalampides & Manoliadis, 2002; Flament *et al.*, 2002; Tarzia *et al.*, 2002; Haack *et al.*, 2004; Ayuso *et al.*, 2004; 2005).

Lead isotopes used for this study are ^{204}Pb , ^{206}Pb , ^{207}Pb and ^{208}Pb . ^{204}Pb is non-radiogenic and ^{206}Pb , ^{207}Pb and ^{208}Pb are formed by the radioactive decay of ^{238}U , ^{235}U and ^{232}Th respectively.

STUDY AREA

Geographical setting

Napoli is located in the Campania Region, along the Tyrrhenian coastline (Fig. 1), in one of the most densely populated and active volcanic areas of the Earth, with a density of about 7,700 inhabitants per km². The climate is typically Mediterranean with an average annual temperature of 15.4 °C and an average rainfall of 1026 mm/y.

The communication network has been expanded considerably in the last few decades, with the construction of motorways, for the increasing traffic that has now practically reached saturation level. In Napoli city between 1991 and 2001, the number of circulating cars grew from *c.* 700,000 to more than 1,500,000 and 30% of them are currently >14 years old.

The metropolitan area of Napoli has become a typical example of intensive human activities affected by various environmental hazards, such as hydrogeological degradation, soil and water pollution, as well as volcanic, seismic and bradyseismic activities.

Geological setting

The geology of the area is dominated by volcanics which erupted since Upper Pleistocene by Mt. Somma-Vesuvius to the east and the Campi Flegrei fields to the west (Fig. 2). The morphology of the metropolitan area of Naples can be subdivided into several flat areas, consisting of reworked pyroclastic terrains, and hills formed by the overlapping of different welded pyroclastic flows (i.e.: Campanian Ignimbrite and Neapolitan Yellow Tuff) (De Vivo *et al.*, 2001b; Rolandi *et al.*, 2003) intercalated with pyroclastic deposits of different origins and ages (i.e., Campi Flegrei, Mt. Somma-Vesuvius, Ischia) (De Vivo *et al.*, 1993; Spera *et al.*, 1998; De Vivo & Rolandi, 2001; De Vivo, 2006). Soils developed on these volcanics, which cover the greater part of the Neapolitan territory, are characterized by andic properties (di Gennaro and Terribile, 1999). The mineralogical assemblage consists mainly of biotite, sanidine, leucite, garnet and pyroxenes (Imperato *et al.*, 2003). In particular, leucite occurs only in the Vesuvian soils.

METHODS

Sampling

Soil samples were collected from 207 sites within a network of an area of about 120 km², with a grid of 0.5 x 0.5 km in the urbanized downtown and 1 x 1 km in the suburban areas (Fig. 1). About 3 kg of soil sample were taken at depths of 15 cm in each sampling location. Soil sampled at different points over an area of about 10 square meters was combined for each location.

The samples consist of 107 residual soils developed on pyroclastic bedrock collected in the suburban areas and 100 soils collected from flower-beds in the downtown area and referred to as non-residual soils. Information from Napoli City Park Authorities indicates that flower-beds have been in place from about 1992 and that they are not fertilized.

Chemical analysis

After being air-dried, the samples were sieved and the <100 mesh fraction (150 µm) was utilized for analyses. Analyses were carried out at the ACME Analytical Laboratories Ltd (Vancouver, Canada), accredited under ISO

Authors: *D. Cicchella, B. De Vivo, A. Lima, S. Albanese, R. A. R. Mc Gill, R. R. Parrish*

9002, by ICP-MS and ICP-AES using Acme's Group 1F-MS package for Ag, Al, As, Au, B, Ba, Bi, Ca, Cd, Co, Cr, Cu, Fe, Ga, Hg, K, La, Mg, Mn, Mo, Na, Ni, Os, P, Pb, Pd, Pt, S, Sb, Sc, Se, Sr, Te, Th, Ti, Tl, U, V, W, Zn by Aqua Regia digestion. Some elements were only determined by ICP-MS (Au, Ga, Hg, Os, Pd, Pt, S, Sc, Se, Te, Tl). Major elements (Al, Ca, Fe, K, Mg, Na, P, Ti) were determined by both instruments (ICP-AES and ICP-MS) but the reported values are from the ICP-AES. Remaining elements (Ag, As, B, Ba, Bi, Cd, Co, Cr, Cu, La, Mn, Mo, Ni, Pb, Sb, Sr, Th, U, V, W, Zn) were determined by both instruments. Trace and ultratrace levels (i.e., < 100 mg/kg) of these elements are reported from the ICP-MS whereas elevated concentrations (i.e., > 100 mg/kg) are reported from the ICP-AES.

Specifically, a 15 g split of powdered soil was digested in 45 ml of Aqua Regia at 95°C for 1 hour. The solution is taken to a final volume of 300 ml with 5% HCl. Aliquots of sample solution are aspirated into a Jarrel Ash Atomcomp 975 ICP-Emission Spectrometer and a Perkin Elmer Elan 6000 ICP-Mass Spectrometer.

Analysis of the same sample solution by both ICP-MS and ICP-AES allows greater accuracy through cross checking and better interference correction in addition to extending the upper range of major elements such as Ca, Fe, P, etc.. Calibration solutions were included at the beginning and end of an analytical run of 40 solutions. Spiking of the sample solution with a tracer element allowed internal standardization. Precision is $\pm 10\%$ at concentrations of 50 times the detection limit or higher. Precision is calculated on three in-house replicates and two blind duplicates submitted by the authors. Accuracy is calculated on Acme's in-house reference material, DS3. Reference material DS3 was calibrated to an Aqua Regia digestion / ICP-MS determination against published values for a concentrated HCl and HNO₃ digestion of Canadian Certified Reference materials (CCRMP) TILL-4 and LKSD-2. The results obtained for these reference materials were consistent with the values obtained from the certification program (e.g., Cu, Pb, Zn, Mo, Ag etc.). The digestion by Aqua Regia is considered to be pseudo-total for the dissolution of metal bound as water soluble salts, in cation-exchange sites, statically bound to clay particles, in organic chelates in amorphous oxides and hydroxides of Mn and Fe, in carbonates, in sulphides and some sulphates. It also partially solubilizes metal in silicates (generally the darker coloured ferromagnesian-rich silicates) and some crystalline oxides of Fe, Ti and Cr.

Table 1 lists the elements analyzed, the instrumental detection limits, the accuracy and the precision of the geochemical data.

Isotope analysis

24 soil samples (Fig. 3) with Pb content > 100 mg/kg were analyzed at the British Geological Survey (BGS, Keyworth, UK) by UV microprobe laser ablation using a VG Elemental P54 Multi-Collector ICPMS (LA-MC-ICPMS) with a VG Elemental Microprobe II Laser system. Analysis of solid samples by LA-MC-ICPMS required minimal preparation: the powdered samples were pressed into pellets and placed in the laser ablation cell. Bulk lead isotope analyses were measured on each pellet comprising 50-100 integrations over a 5 x 3 mm raster grid using a repetition rate of 20Hz, 30-65% power and a spot size of 200-400 µm (depending sample heterogeneity and concentration). This avoids lengthy digestions and chemistry, which may be incomplete and can also potentially introduce sample contamination. Correction of instrumental mass bias was made by aspirating thallium solution through the laser cell during analyses, and ^{202}Hg was monitored during analyses to allow ^{204}Hg to be subtracted from ^{204}Pb measurements.

The NBS-981 standard value obtained (after the above corrections were applied) during repeated runs was: $^{206}\text{Pb}/^{204}\text{Pb} = 16.938$, $^{207}\text{Pb}/^{204}\text{Pb} = 15.491$, $^{208}\text{Pb}/^{204}\text{Pb} = 36.691$ with a precision of about 0.05% (2σ). Accepted values for NBS 981 are $^{206}\text{Pb}/^{204}\text{Pb} = 16.9356$, $^{207}\text{Pb}/^{204}\text{Pb} = 15.4891$, $^{208}\text{Pb}/^{204}\text{Pb} = 36.6996$ (Todt *et al*, 1996). Internal reproducibility is given by a matrix matched soil pellet which was also used as an in-house standard giving $^{206}\text{Pb}/^{204}\text{Pb} = 18.373$, $^{207}\text{Pb}/^{204}\text{Pb} = 15.620$, $^{208}\text{Pb}/^{204}\text{Pb} = 38.291$ with a precision of circa 0.05% (2σ) for the first two ratios but nearer 0.15% (2σ) for $^{208}\text{Pb}/^{204}\text{Pb}$ possibly due to a transient organic interference. The Pb isotopic composition of analyzed samples are reported in Table 2.

Statistical analysis

Univariate and multivariate analyses were carried out in order to show the single-element geochemical distribution and the distribution of factor scores of the elemental associations resulting from R-mode factor analysis. The statistical parameters of the univariate analysis are reported in table 3. For statistical computation, the data below the instrumental detection limit (IDL) was assigned a value corresponding to 50% of the detection limit. The data distribution was generally positively skewed, so, to normalize it, we converted the data into their logarithm values.

Factor analysis was used to develop different groups of chemical elements with approximately the same geochemical pattern. Factor analysis is a statistical method that extracts the most important information from the data because it is based on the concept of communality (for each variable, communality is defined as the common variance explained by the factors). In order to facilitate the interpretation of results, varimax rotation

was used because it is an orthogonal rotation that minimizes the number of variables that have high loading on each factor, simplifying the interpretation (Reimann *et al.*, 2002). The different factors obtained were studied and interpreted in accordance with their hypothetical origin (natural, anthropogenic or mixed).

R-mode factor analysis has been performed using GRFAC software (Miesh, 1990) on a matrix containing 35 elements. The chemical elements with an elevated percentage (>5%) of analytical determinations below the instrumental detection limit were not considered for factor analysis. The four-factor model, accounting for 78.5 % of the data variability, deemed appropriate for Neapolitan volcanic soil data is shown in Table 4. Elements with loadings over |0.5| are considered as representative members of each association that results from the chosen factor model. The element association **F1** (Pb-Sb-Ag-Au-Cd-Cr-Zn-P-Hg-Ni-Cu-Ca-Mo-Ba) accounts for 51.6% of total data variability while the **F2** association (Ga-La-Al-Ti-Tl-Th-U-Sc-Co) accounts for 28.6% of total data variability; **F3** (Na-Sr-K-B-Mg-Ca-Mo-V-Ba) and **F4** (As-Mn-Fe-W-Bi-Te-V) account for 12.4 % and 7.4 % of total data variability respectively. In each association, elements are listed with decreasing loadings (Table 4).

Geochemical mapping

Maps showing Pb and the four association factor score distributions have been obtained using GeoDAS and ArcView GIS software. Multifractal Inverse Distance Weighted (IDW) is the interpolation method used with a search distance of 1 km and map resolution of 150 m (for more details about this methodology see Cheng, 2000; Lima *et al.*, 2003a; Cicchella *et al.*, 2005).

RESULTS AND DISCUSSION

Heavy metal distribution

For the sake of conciseness, only distribution maps of Pb (Fig. 3) and the factor scores for the four element associations (Fig. 4), obtained by R-mode factor analysis, are presented here. Geochemical maps showing concentration distribution of all the analyzed elements are published in De Vivo *et al.* (2006).

The interpolated Pb distribution map (Fig. 3) shows that the highest values (>325 mg/kg) are mostly located in the central and eastern part of Napoli city. These areas are highly urbanized and more industrialized compared with the western part. Pb concentrations decreased gradually from the centre to the city boundary. Corresponding background values, obtained from uncontaminated soils of volcanic and non-volcanic origin (Cicchella *et al.*, 2005), vary in the range 40 - 80 mg/kg.

Maps of the factor score distributions are very useful to correlate lithologies with physico-chemical and pollution processes of the surface environment at each sampled site. Figure 4 shows, for each association identified by the factor model 4, an interpolated distribution map of factor scores. These maps fit well with the distribution of the single elements that have a high loading in this association. This can be seen comparing the Pb interpolated map (Fig. 3) with F1 factor scores (Fig. 4) map, where Pb has a very high loading (0.9). The association F1 (Pb-Sb-Ag-Au-Cd-Cr-Zn-P-Hg-Ni-Cu-Ca-Mo-Ba), accounting for 51.6% of total data variability, is explained by elements introduced in the environment by human activities. The factor scores distribution (Fig. 4) is, hence, clearly dominated by anthropogenic sources. The very high values (between 1 and 2.2) coincide exactly with the international airport area, the eastern industrial area and Napoli city centre, characterized by heavy daily traffic jams (Fig.1).

The western portions of the urban area, with least industrial and commercial influence, are practically uncontaminated. They are characterized by negative factor scores which means that the sampled sites are depleted in the elements of the association. In this western area, the concentration values of the single harmful elements of F1 association (e.g., Fig. 3) do not exceed the local geochemical backgrounds (Cicchella *et al.*, 2005).

The F1 association includes most of the harmful elements (Pb, Sb, Cd, Cr, Zn, Hg, Ni and Cu) which have national intervention levels fixed by the Italian environmental Law 471/1999 (Table 5). Figures 5 and 6, show cumulative frequency curves for each element listed in Table 5, and for comparison a range of background values are marked with the grey shading from Cicchella *et al.* (2005) and De Vivo *et al.* (2006). In these figures, the cumulative percent value (a) is corresponding to the residential/recreational intervention limit; the cumulative percent value (b) is corresponding to the commercial/industrial intervention limit. Many of the samples collected in this study are characterized by harmful element concentrations exceeding the limit recommended for residential and recreational area. This is true particularly for Pb and Zn. Figure 5F shows that 62% of sampled soils have Pb concentrations greater than 100 mg/kg (residential/recreational intervention limit) and 2% exceed 1000 mg/kg (Pb commercial/industrial intervention limit). The majority of sampled soils (73%) have a Pb content that exceed the local background values. For Zn, 55% of samples (Fig. 5H) have concentrations greater than 150 mg/kg (residential/recreational intervention limit) and about 70 % exceed the local background values. With exception of Cr and Ni (Figs. 5B and 5E), the concentration of the other harmful elements of F1 association: Cd, Cu, Hg and Sb (Figs. 5A, 5C, 5D, 5G) also exceed the Italian intervention limits for residential/recreational areas. On the basis of the percentage of samples that exceed background values (Fig. 5

and Table 5) for all the harmful elements which contribute to this factor association, urban surface soils are most significantly enriched in Pb, Hg, Zn, Sb, and to a lesser extent in Cu, Cd, Cr and Ni. Leaded petrol is the most probable source for the Pb enrichment, whereas tyre wear may be the main source for Zn (Muschack, 1990).

Factor scores distribution for the F2 association (Ga-La-Al-Ti-Tl-Th-U-Sc-Co), accounting for 28.6% of total data variability, clearly divides Napoli city area in two sectors: the eastern one with high factor scores (from 0.9 to 2.3) and the western one with negative values (Fig. 4). The local geology controls the covariation between the elements of this association with Mt. Somma-Vesuvius volcanics outcropping in the eastern part of Neapolitan area, whereas Ignimbrites and Campi Flegrei volcanics occur to the west. These lithological differences are also defined by the factor score distribution of the F3 association. Tl, however, is an important element of the association (F2), and 65% of sampled soils (Fig. 6C) have concentration values above the residential/recreational limit (1 mg/kg). But, as shown by Cicchella *et al.* (2005) and De Vivo *et al.* (2006), the Tl background values (0.5-1.5 mg/kg), obtained from uncontaminated Neapolitan volcanic soils, are higher than the residential/recreational intervention limits fixed by the Law 471/1999 (Fig. 6C). This finding indicates that intervention limits fixed by the legislation should be modified to take into account the elevated background values found in volcanic areas such as the “Neapolitan Province”.

The factor score distribution for the F3 association (Na-Sr-K-B-Mg-Ca-Mo-V-Ba), accounts for 12.4% of total data variability, and clearly differentiates the soils developed on the Mt. Somma-Vesuvius volcanics as opposed to those that develop on Campi Flegrei volcanic field. This element association could be used as a lithological marker since high factor scores values (from 0.5 to 2.6) distinctly characterize the Mt. Somma-Vesuvius lithologies, whereas low values (from 0.5 to -1.9) characterize the Campi Flegrei volcanics and other lithologies (Fig. 2). The only exceptions to this generalisation are the high factor scores (from 0.5 to 2.6) occurring on the western sector of the territory, in the Bagnoli area, where the influence of the hydrothermal activity plays an important role (Tarzia *et al.*, 2002).

The F4 association (As-Mn-Fe-W-Bi-Te-V), accounts for 7.4% of total data variability, and shows higher factor scores (> 0.8) in the Bagnoli area. The elevated concentrations of elements from this association in the Bagnoli soils are derived from a natural origin and can be explained by the occurrence of Fe and Mn hydroxides which can adsorb and co-precipitate with of metallic elements, such as As, W, Bi, Te and V. Arsenic concentrations in Bagnoli soils (Cicchella *et al.*, 2005) reach 164 mg/kg (Fig. 6A) well above the background value of 18 mg/kg, the residential/recreational intervention limit of 20 mg/kg, and the commercial/industrial intervention limit of 50 mg/kg. The existence of this natural As-enrichment is due, to the hydrothermal activity

in the Bagnoli area, as discussed before, where many active fumaroles and springs occur. High concentrations of As and other metallic elements (e.g. As up to 8000 µg/l) are reported in thermal waters from spas of the Campi Flegrei by other authors (Dall'Aglio *et al.*, 1970; Celico *et al.*, 1992; Tarzia *et al.*, 2002). Thermal activity has resulted in enrichment of As, Mn and other elements that are mobile under hydrothermal conditions. This metal enrichment is typical of spring and spas active in volcanic geothermal systems (Mc Kibben & Elders, 1985; Goff *et al.*, 1994). This is also confirmed in the waters of spas of the volcanic area of Ischia island (e.g., As average = 155 µg/l, with values up to 1500 µg/l; Lima *et al.*, 2003b).

Isotopic signatures of Pb sources

Table 2 shows measured Pb isotope ratios for the selected soil samples (with Pb content > 100 mg/kg). Values range between 0.852 - 0.883 for $^{207/206}\text{Pb}$ and 2.064 - 2.120 for the $^{208/206}\text{Pb}$. In fig. 7A $^{207/206}\text{Pb}$ ratios have been plotted against $^{208/206}\text{Pb}$ ratios, and show a linear trend with a significant regression coefficient ($R^2 = 0.91$).

In the simplest interpretation, this suggests mixing has occurred between two end-member Pb sources of different Pb isotope composition; one of clear natural origin (geogenic) and another of anthropic nature. In figure 7B $^{207/206}\text{Pb}$ ratios, plotted against $^{208/206}\text{Pb}$ ratios, show the studied Neapolitan soil data, the European gasoline Pb isotope data (Monna *et al.*, 1999; Teutsch *et al.*, 2001), representing a possible anthropogenic component, the Neapolitan volcanic Pb isotope signature (Ayuso *et al.*, 1998; Gilg *et al.*, 2001; Somma *et al.*, 2001) and Pb isotope values for the Neapolitan Yellow Tuff (NYT) (D'Antonio *et al.*, 1995), which represent the natural component (geogenic). This figure (7B) clearly confirms that Neapolitan soil data (field B) form a mixing line between two components: geogenic (field A) and anthropogenic (field C), with the anthropogenic component dominated by petrol Pb. Soil compositions also show an overlap with the anthropogenic field indicating that the latter component is dominant compared with the geogenic (natural) one, as one would expect for higher Pb concentrations. Fig. 8 showing $^{207/206}\text{Pb}$ versus $^{206/204}\text{Pb}$ also demonstrates that Neapolitan soils have mixed Pb isotope compositions. They fall between the Pb isotope compositions of geological materials (bedrocks) (Ayuso *et al.*, 1998; Gilg *et al.*, 2001; Somma *et al.*, 2001) and an anthropogenic end member dominated by Pb from motor vehicle emissions (Keinonen, 1992). Overlap of the Neapolitan soil Pb isotope trend with anthropogenic compositions indicate that the anthropogenic isotope contribution prevails in a mixing pattern of the two Pb sources. This is further demonstrated by plotting $^{207}\text{Pb}/^{206}\text{Pb}$ ratios versus Pb log-concentrations (Fig. 9). The plot shows a strong correlation between elevated concentrations of Pb and high $^{207/206}\text{Pb}$ isotope ratios, which are

typical of the Pb added to the European gasoline (Monna *et al.*, 1999; Teutsch *et al.*, 2001). This indicates that a large part of the Pb, present in excess in the Neapolitan soils, is derived from leaded gasoline combustion.

In the last 10 years levels of Pb pollution have certainly decreased because of the elimination of leaded gasoline, but new pollutants have been introduced in urban areas: the platinum elements related to the use of catalytic exhausts. It has been, in fact, demonstrated that Pd and Pt concentrations in the Neapolitan soils are already high (Cicchella *et al.*, 2003).

CONCLUSIONS

The main conclusion of this research is that Pb concentrations and the distributions of metal associations factor scores, resulting from R-mode factor analysis, combined with Pb isotope data, are powerful indicators for monitoring the pollution of urban soils. Neapolitan urban soils are significantly enriched in Pb, Hg, Zn, Sb, and to a lesser extent in Cu, Cd, Cr and Ni.

Pb isotope investigation demonstrates that road traffic is one of the main sources of metal pollution. Pb isotope compositions for the Neapolitan urban area soils form a trend indicative of mixing between two end-members, one of clear natural origin (geogenic) and another related to human activities (anthropogenic). The latter component is dominant and increases with increasing Pb concentration. Uncontaminated samples fall in the geogenic field for Pb isotope ratios and are characterized by high F4 (As-Mn-Fe-W-Bi-Te-V) association factor scores. Enrichment of these elements is controlled by natural sources (Fe and Mn hydroxides absorption and co-precipitation phenomena) and are closely related to the existence of natural As-pollution due to hydrothermal activity. This was particularly demonstrated in the Bagnoli brownfield site where many active thermal springs occur (Tarzia *et al.*, 2002).

The concentration levels of many of the investigated elements are well above the intervention limit fixed by the Italian environmental Law 471/1999 (Cicchella *et al.*, 2005; De Vivo *et al.*, 2006). The levels of these pollutants are not of concern in the suburban areas, but in some places, particularly in the historic center and in the eastern industrialized area, concentrations are above the maximum acceptable limits, for residential/recreational land use and in some instances for industrial/commercial land use. This means, as dictated by Law 471/1999, that some of the areas we have identified through this study should be delimited and closed for safety purposes in order to guarantee the health of the people who live there. Remediation of these soils should be carried out by the local Authorities to eliminate the source of the harmful pollutants.

Table 1. *Detection limits, accuracy error and precision.**

**The laboratory accuracy error was been determined using the following formula:*

$$\text{Accuracy error} = (|X - TV| / TV) * 100$$

where

X = laboratory's analysis result for the performance sample (standard DS3)

TV = true value of the performance sample (standard DS3)

Precision was been calculated as Relative Percent Difference (%RPD) with following formula:

$$\%RPD = [(|SV - DV|) / (SV + DV) / 2] * 100$$

where

SV = the original sample value

DV = the duplicate sample value

Table 5. Background concentration values for harmful elements in Neapolitan volcanic soils (Cicchella *et al.*, 2005; De Vivo *et al.*, 2006b) and Italian intervention criteria for soils (D.M. 471/1999).

Elements	Background values in Neapolitan soils (mg/Kg)	Residential/recreational intervention limits (mg/Kg)	Industrial/commercial intervention limits (mg/Kg)
Antimony	0.2 – 1.1	10	30
Arsenic	6 - 18	20	50
Cadmium	0.1 – 0.5	2	15
Cobalt	3 - 17	20	250
Chromium	1 - 16	150	800
Mercury	0.01 – 0.10	1	5
Nickel	1 – 19	120	500
Lead	20 - 80	100	1000
Copper	4 – 100	120	600
Selenium	0.1 – 0.4	3	15
Thallium	0.5 – 1.5	1	10
Vanadium	30 – 75	90	250
Zinc	35 - 100	150	1500

FIGURE CAPTIONS

Figure 1. Traffic flow and sample sites map.

Figure 2. Schematic geological map of metropolitan area of Napoli

Figure 3. Pb interpolated data distribution

Figure 4. Factor scores association maps from soils of metropolitan area of Napoli.

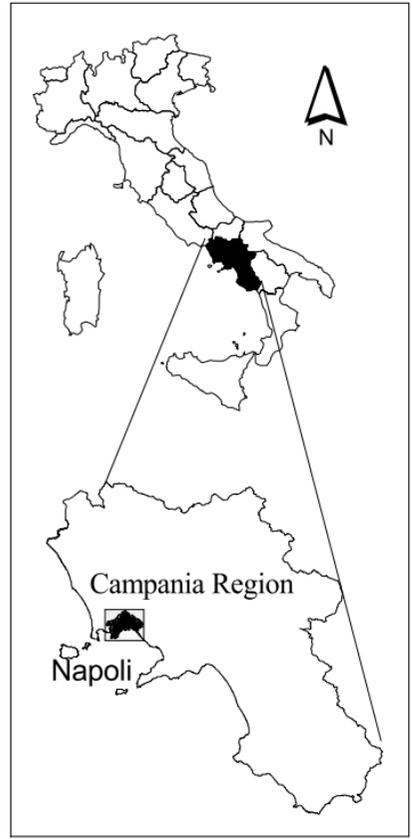

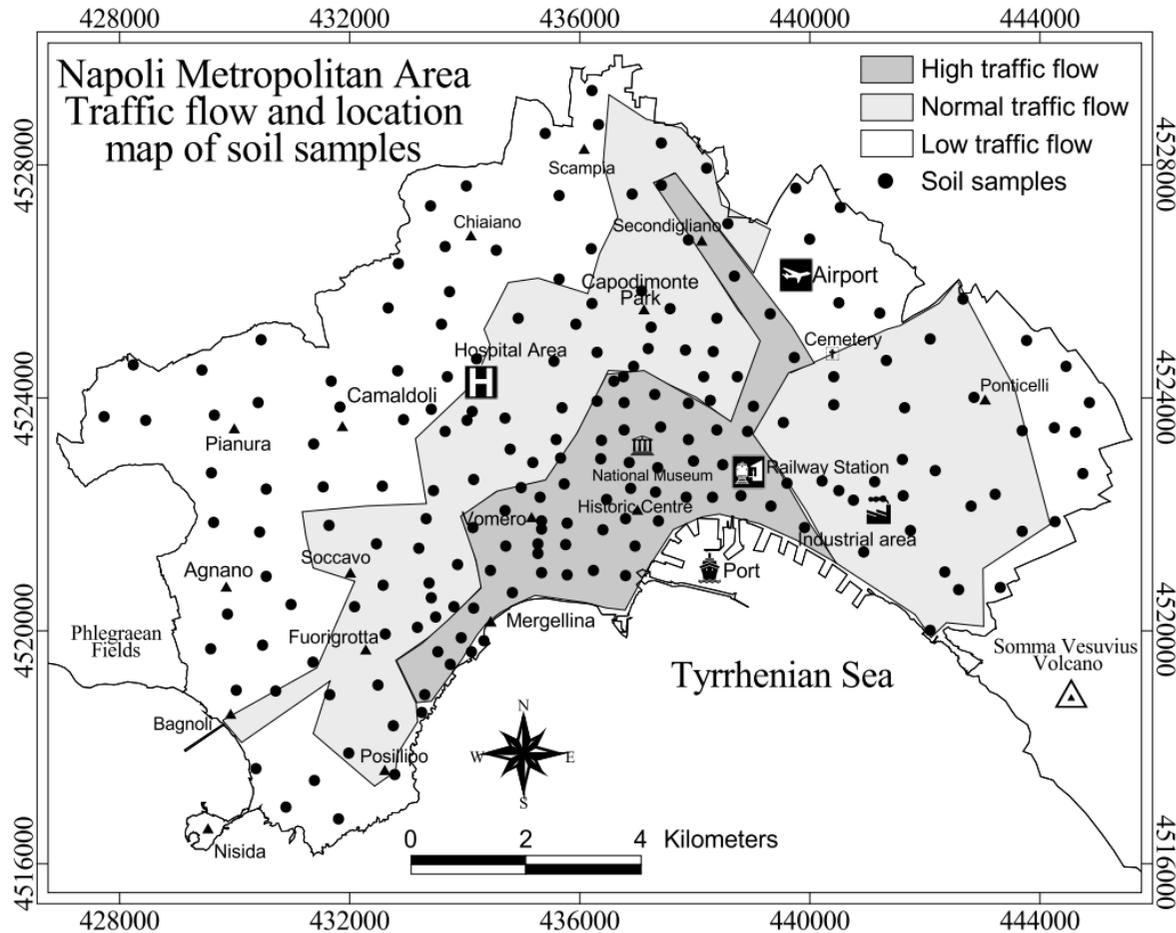

Figure 5. Cumulative frequency curves for Cd, Cr, Cu, Hg, Ni, Pb, Sb, Zn,. The graphs also report the range of background values marked with the grey bands. The percent cumulative value (a) corresponding to the residential/recreational intervention limit; the percent cumulative value (b) corresponding to the commercial /industrial intervention limit.

Figure 6. Cumulative frequency curve for As, Co, Tl and V.

Figure 7. A - Plot of $^{207}\text{Pb}/^{206}\text{Pb}$ vs. $^{208}\text{Pb}/^{206}\text{Pb}$. In the diagram are also reported the 2σ errors and the regression coefficient (R^2). **B** - $^{207}\text{Pb}/^{206}\text{Pb}$ vs. $^{208}\text{Pb}/^{206}\text{Pb}$ isotopic composition of samples collected in this study and data reported in literature. Data sources: Monna *et al.*, 1999; Teutsch *et al.*, 2001; Ayuso *et al.*, 1998; Gilg *et al.*, 2001; Somma *et al.*, 2001, D'Antonio *et al.*, 1995.

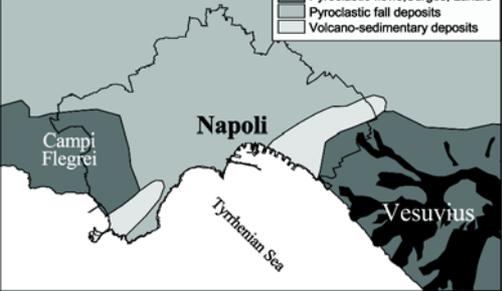

Figure 8. Plot of $^{206}\text{Pb}/^{204}\text{Pb}$ vs. $^{207}\text{Pb}/^{206}\text{Pb}$. In the diagram are reported isotopic composition of samples collected in this study and data reported in literature. Data sources: Keinonen, 1992; Ayuso *et al.*, 1998; Gilg *et al.*, 2001; Somma *et al.*, 2001.

Figure 9. Pb Log-concentration plotted against $^{207}\text{Pb}/^{206}\text{Pb}$ isotopic ratio of samples collected in this study and in south-western area of Napoli (Bagnoli) (from Tarzia *et al.*, 2002).
