# Hydrological Summary for Great Britain 

## NOVEMBER 1992

## Rainfall

Around $140 \%$ for Britain as a whole and notably wet late in the month. A fifth successive wet month has terminated the meteorological drought in all regions. Modest long term deficiencies can still be recognised in the English lowlands. Rainfall accumulations in the longest timeframes ( $>2$ years) are outstandingly high for western Scotland.

## River flows

Generally, flows increased markedly through the month and November runoff totals were well above average except in some permeable eastern and southern catchments. Flooding was widespread in southern Britain at month-end and autumn runoff totals are notably high over wide areas. Many springs are flowing again for the first time in at least two years.

## Groundwater

Sustained rainfall on saturated catchments produced heavy infiltration in November and early December - approaching the annual average recharge in some areas. Some very notable groundwater level rises have been reported but the lag between infiltration and water-table response (many weeks in some deep wells) means that the full impact of the autumn rainfall will not be evident before year-end.

## General

Exceptionally unsettled weather conditions over the latter half of November shifted the focus of hydrological concern from drought conditions to floods. A remarkably protracted drought has been effectively terminated in almost all areas. However, at least average rainfall through the remainder of the winter half-year will be required to restore some groundwater levels to within the normal range.

## HYDROLOGICAL SUMMARY FOR GREAT BRITAIN - NOVEMBER 1992

Data for this report have been provided principally by the regional divisions of the National Rivers Authority in England and Wales, the River Purification Boards in Scotland and by the Meteorological Office. Reservoir contents information has been supplied by the Water Services Companies, the NRA or, in Scotland, the Lothians Regional Council. The most recent areal rainfall figures are derived from a restricted network of raingauges (particularly in Scotland) and a proportion of the river flow data is of a provisional nature.

A map (Figure 4) is provided to assist in the location of the principal monitoring sites.

#### Abstract

Rainfall November was a notably mild and very wet month in most regions. Weather patterns were dominated by a sequence of active frontal systems carried on a westerly or south-westerly airstream. The exceptionally unsettled conditions, particularly towards month-end, resulted in the focus of hydrological concern shifting from droughts to floods as saturated catchments and sustained rainfall produced widespread spate conditions.

Following a typically autumnal start to the month, November became increasingly unsettled. Some districts in southern Britain recorded rainfall on every day from the 13th and hefty totals were registered around the 14th, 25th and at month-end. Monthly rainfall totals comfortably exceeded the November average in almost all regions with parts of south-western Britain recording more than twice the 1941-70 mean. Rainfall totals exceeding 100 mm for the four days beginning on the 29th were common in the West Country and in central and southern Wales; at Tyn y Waen a fall of 109 mm on the $29 \mathrm{th} / 30 \mathrm{th}$ was followed by 106 mm on the $1 \mathrm{st} / 2 \mathrm{nd}$ December - return periods of 15 and 25 years respectively have been associated with the two storms. A few eastern areas from Lincolnshire to north-east Scotland, mostly where rain-shadow effects could be recognised, failed to reach the November average but the shortfalls were generally marginal. In some areas, November was the wettest month since February 1990 and amongst the half dozen wettest months in the last decade.

For England and Wales as a whole, November was the fifth successive month with above average rainfall, the longest such sequence since the summer of 1985. The July-November period was the second wettest since 1960, more importantly - in the drought context - the rainfall favoured eastern areas for much of this time. In many lowland districts, June was the only month to record below average rainfall since February. For the Thames Valley, the accumulated rainfall total over the five months to November was the fourth highest in a 110-year record (only 1960 was significantly wetter). Over much of the English lowlands provisional data suggest that the autumn rainfall exceeded that which rapidly terminated the 1984 drought and, in parts of East Anglia especially, also eclipsed the abundant rainfall which provided a dramatic conclusion to the drought of 1975/76. A particularly rapid transformation in the severity of the lowland drought was signalled by the notable storm of the 20/21st September. This marked the start of an 11-week period when rainfall in much of eastern England approached 50 per cent of the 1941-70 annual average and also approached 11-month totals registered at the height of the drought.

The accumulated rainfall totals presented in Table 1 and 2 confirm the moderation in the severity of the lowland drought since the late spring and its rapid decline in recent months. For the first time since the winter of 1989/90 notably high ' $n$-month' rainfall totals may now be identified in eastern England. In rarity terms, these are of minor significance compared with the remarkably abundant rainfall in western Scotland over the last four years.

## Evaporation and Soil Moisture Deficits (SMDs)

Provisional data indicate that last month was the eighth warmest November this century and the warmest since 1978. For the first time in more than 10 years November was warmer than October. Potential evaporation (PE) totals for November rank very high in the MORECS series (from 1961) but losses were generally only $5-10$ millimetres above average. Although autumn as a whole was cooler than average, PE totals for 1992 thus far remain substantially above average, but well short of the record totals computed for 1989 and 1990. By contrast, 1992 actual evaporation totals are much greater than for 1989 and 1990, in the lowlands especially. In some districts the relatively moist summer soil conditions have allowed AE totals to exceed the previous highest on record.

Soils were wet throughout virtually the whole of Britain by mid-November and water-logged conditions were common from around the 23rd. At the same time in the previous four years very significant lowland deficits remained. The early elimination of SMDs in 1992 has permitted the seasonal recovery in runoff and recharge rates to proceed far more briskly than in any autumn since 1987. The prospect, given average rainfall, of groundwater replenishment extending over around six months (six weeks being more typical in recent years) in the eastern lowlands is very encouraging in relation to the 1993 water resources outlook.

## Runoff

The recovery in lowland river flows which generally began in late September gathered momentum in November and by month-end spate conditions characterised all but the most permeable catchments. In the West Country the steep increase in flows in late-October was followed by further increases in November culminating in widespread floodplain inundation around month-end. The River Exe recorded its highest flow for a decade but generally the flooding was notable for its areal extent rather than its magnitude. Flooding was more severe in South Wales where new peak discharge rates were recorded on the Gwili (which has a 24 -year record) and Ewenny ( 21 -year). Notable peaks were also registered on rivers draining from the Brecon Beacons. Very high flows occurred on, for example, the Taff, Rhymney and Sirhowy and significant flood damage was sustained in Tredegar and Pontypridd. An added danger was the slumping of coal tips caused by sustained heavy rainfall. Overall, the flooding was significantly less severe than in 1979 but, as elsewhere, transport disruption was considerable. Flood alerts were called on many rivers in central and southern Britain and inundation of agricultural land was widespread. An unusual feature reported from a number of Chalk catchments was localised flooding in headwater reaches. This was more a consequence of surface (or near-surface) runoff than baseflow recoveries but a further factor is the reduction in channel capacities due to vegetation growth in stream beds which - in some areas - have been dry for over two years.

November runoff totals were above average throughout almost the whole of Great Britain, notably so to the south of a line from the Wash to Cardigan Bay. In eastern England the hydrological contrast with the recent past was very notable. In some catchments runoff totals exceeded the monthly average for the first time in over four years; examples include the Little Ouse at Abbey Heath which fell below average in May 1988. The Thames recorded its highest monthly flow since significant flooding last occurred in February 1990; above Oxford the recent water levels exceeded those of 33 months ago. Although individual daily flows at the Kingston gauging station over the fortnight beginning on the 26th November were unexceptional, the accumulated gauged runoff was roughly comparable to the overall totals for the May-December period in both 1990 and 1991.

Autumn runoff totals provide clear evidence for the drought's termination, in river flow terms, throughout most of the region where drought severity was extreme in the early spring. The September to November runoff total for the Bedford gauging station (on the Ouse) was four times the average and the highest in a record from 1933; autumn flows were also amongst the highest on record for the Trent, Witham, Colne - see Table 3. Flow recoveries have been less dramatic in some of the most permeable catchments but over the last six weeks many springs have begun to flow once again and the stream network has extended further into the headwaters. Although long term accumulated runoff totals remain relatively depressed for some spring-fed rivers (e.g. the Itchen for which the January-November 1991 runoff is the lowest on record) average winter rainfall should ensure healthy flows by next spring.

Reservoir replenishment continued throughout November with a considerable number of gravity-fed upland impoundments drawn-down to provide a measure of flood alleviation storage. (Keilder storage was also reduced to provide scope for further habitat creation.) Entering December, regional storage totals were near capacity and very healthy relative to the early winter storages in each of the last three years in the lowlands.

## Groundwater

Sustained and often heavy rainfall, combined with saturated soils have created ideal conditions for heavy infiltration over the last six weeks or so. Preliminary estimates suggest that autumn infiltration in much of the English lowlands exceeds the, admittedly modest, total for the entire 1991/92 recharge season and may in some areas exceed the long term annual average. For the deeper Chalk wells many weeks may elapse before surface infiltration translates into a rise in groundwater levels; this lag is a particularly important factor when recoveries need to be generated from an exceptionally low level.

Groundwater levels are now rising in all the index wells, although the rate of recovery varies greatly from area to area. Upturns in parts of the Chalk are as yet barely discernible but have begun very much earlier than in the last four years. Some very sharp increases in level have also been reported levels at Chilgrove (not illustrated), for example, rose nine metres in the week ending on the 1st December. In the LincoInshire Limestone, at the New Red Lion site, and the Stone site (PermoTriassic sandstones) in the Midlands, levels are approaching the seasonal recorded maxima. The same is true of the Alstonfield borehole where levels have increased around 30 metres through the autumn. Most of the sites in central and southern England show water-tables approaching or above the seasonal means.

The relicts of the drought are still evident. In the Permo-Triassic sandstones, the Weeford Flats site remains dry, the water-table presumably not yet having risen above the bottom. At Dalton Holme and Little Brocklesby, groundwater levels remain near the seasonal minima. At Washpit Farm and Redlands Hall in East Anglia and at Llanfair DC in north Wales, levels have yet to rise above the seasonal minima (but note, that levels at the latter two sites were recorded early in November). In the South-West, levels at the Bussels site remain close to the seasonal minimum.

The recharge to the country's aquifers has already been substantial, and in all probability the intense rainfall of late November and early December has yet to register its full effect on the water-table, particularly in those regions where groundwater levels have been most severely depressed and their response to infiltration correspondingly slow. Given average rainfall over the winter and extending through to April, recharge over much of the drought affected regions should exceed about 150 per cent of the long term average. This would allow groundwater resources to recover to near, or above, mean values before the onset of the summer recession in 1993.

In the October summary, a tentative suggestion was put forward for the determination of the end of the groundwater drought; the proposed definition was for groundwater levels in relevant index wells to reach and remain at or above mean seasonal values for two successive months. Over central and southern Britain, these conditions may well be met by the end of 1992. In the deeper wells of Yorkshire, Humberside, East Anglia, north Wales and south-west England, they should be met by the end of March providing that the spring rainfall is not substantially below average. The curtain may then finally fall on a drought which, in meteorological terms, began to ameliorate in March 1992.

Return period assessments are based on tables provided by the Meteorological Office*. These assume a start in a specified month; return periods for a start in any month may be expected to be an order of magnitude less - for the longest durations the return period estimates converge. "Wet" return periods underlined.
The tables reflect rainfall totals over the period 1911-70 only and the estimate assumes a sensibly stable climate.

* Tabony, R.C., 1977, The Variability of long duration rainfall over Great Britain, Scientific Paper No. 37, Meteorological Office (HMSO).

Notes:
(i) Values based on gauged flow data unless flagged (natr.), when naturalised data have been used.
(ii) Values are ranked so that lowest runoff as rank 1
(iii) sLT means percentage of long term average from the start of the record to 1991. For the long periods (at the right of this table), the end date for the long term is 1991.

- Live or usable capacity (unless indicated otherwise)

77* Kielder drawn down for conservation purposes

* Gross storage/percentage of gross storage

1. Includes Haweswater, Thirlmere, Stocks and Barnacre.
2. Cow Green, Selset, Grassholme, Balderhead, Blackton and Hury.
3. Howden, Derwent and Ladybower.
4. Swinsty, Fewston, Thruscross and Eccup.
5. The Nidd/Barden group (Scar House, Angram, Upper Barden, Lower Barden and Chelker) plus Grimwith.
6. Lower Thames (includes Queen Mother, Wraysbury, Queen Mary, King George VI and Queen Elizabeth II) and Lee Valley (includes King George and William Girling) groups pumped storages.
7. Farmoor 1 and 2 - pumped storages.
8. Blagdon, Chew Valley and others.
9. Shared between South West (river regulation for abstraction) and Wessex (direct supply).
10. Usk, Talybont, Llandegfedd (pumped storage), Taf Fechan, Taf Fawr.
11. Claerwen, Caban Coch, Pen y Garreg and Craig Goch.

Note: Variations in storage depend on the balance between inputs (from catchment rainfall and any pumping) and outputs (to supply, compensation flow, HEP, amenity). There will be additional losses due to evaporation, especially in the summer months. Operational strategies for making the most efficient use of water stocks will further affect reservoir storages. Table 4 provides a link between the hydrological conditions described elsehwere in the report and the water resources situation.

FIGURE 3 GROUNDWATER LEVEL HYDROGRAPHS
