## Hydrological Summary for Great Britain

## APRCL 1991

## Rainfall

The April total for GB approached $120 \%$ of the 1941-70 average but spatial variations were large and rainfall was very unevenly distributed through the month.

## River flows

Spate conditons characterised western Scotland and runoff totals were above average or well within the normal range throughout most of Britain. However flows - and particularly long term runoff accumulations - remain very low in parts of the English lowlands albeit usually above historical drought minima.

Groundwater Levels
Away from the eastern lowlands water-tables have recovered appreciably since late-1990. By contrast groundwater levels in a substantial proportion of the eastern Chalk outcrop are close to the minimum on record.

## General

The area subject to severe drought conditions has decreased greatly since the late-autumn of 1990. Additionally, in most regions, the hydrological and water resources outlook is appreciably more encouraging than in May 1990. Concern currently focuses on a zone from Lincolnshire to Kent where long term rainfall deficiencies have resulted in exceptionally low groundwater levels with. now, little realistic prospect of further significant recharge before the autumn.

## HYDROLOGICAL SUMMARY FOR GREAT BRITAIN

APRIL 1991

Data for this report have been provided principally by the regional divisions of the National Rivers Authority in England and Wales, the River Purification Boards in Scotland and by the Meteorological Office. Reservoir contents information for England and Wales has been supplied by either the Water Services Companies or the NRA. The recent areal rainfall figures are derived from a restricted network of raingauges (particularly in Scotland) and a proportion of the river flow data is of a provisional nature.

A map (Figure 4) is provided to assist in the location of the principal monitoring sites.

## Rainfall

Weather patterns in April were typically capricious - a few warm interludes punctuated extended periods dominated by cool, overcast conditions. Relatively dry conditions - with light, patchy showers bringing meagre rainfall to the lowlands - obtained throughout the greater part of the month. However, widespread and persistent rainfall occurred during the first week and also on the 29/30th when an exceptionally slow moving depression tracked eastwards across southern Britain bringing continuous, moderate rainfall over periods of up to 30 hours. For some localities in the South-East, the 29 th ( $09.00-09.00$ ) was the wettest April day this century.

The within-month temporal contrasts in rainfall were allied to considerable spatial variability. Parts of the west coast of Scotland recorded up to twice the April average whereas along England's northeastern seaboard totals of around half the mean were more typical. Some accentuation in the normal west-to-east rainfall gradient could also be recognised in southern Britain but local variability was considerable especially in those eastern districts where the drought remains most severe.

On a regional basis provisional rainfall figures indicate that for 1991 thus far, and for the period beginning in December 1990, accumulated totals have generally been a little above average (the Anglian region is an exception). Rainfall over the last four to six months has served to greatly reduce, albeit sluggishly, the areal extent of the drought in England and Wales. Overall, the amelioration was maintained in April but the improvement in parts of the lowlands was rather marginal and in a few districts, for instance in Lincolnshire, rainfall deficiencies actually increased.

Longer term rainfall accumulations (Table 2) emphasise the exceptional wetness of parts of Scotland and the remarkable spatial variation throughout Great Britain. Only very modest droughts can be recognised away from the English lowlands where the rainfall figures confirm that the current drought is primarily a legacy of the large rainfall deficiencies established in 1990, 1989 and, in some areas, 1988. The very extended nature of the drought is evident from the accumulations presented in Table 2 which identifies the Anglian, Thames and Southern regions as suffering the greatest long term deficiencies. For the Thames region, the rainfall total for the 14 months from March 1990 is only a little above the minimum on record (for that specified period) - approximately 560 mm registered in both $1943 / 44$ and 1975/76. Importantly, the three-year accumulation is also comparable with the lowest on record; in this timeframe the major rainfall deficiencies beginning in 1899, 1919, 1941, 1962 and 1971 provide reasonably close analogies and more realistic comparative yardsticks than the more intense but less durable droughts of, for instance, 1959, 1975/76 and 1984.

## Evaporation and Soil Moisture Deficits (SMDs)

Temperature and sunshine hours for April were well within the normal range throughout Great Britain. Correspondingly, evaporative losses were close to the long term mean and typically a little below those calculated for April 1990. The return to more familiar winter temperatures since the end of last year, has left accumulated evaporation totals for 1990/1991 appreciably below the (often record) totals established for the corresponding periods in 1989/1990.

Soil moisture conditions varied considerably throughout the month but - entering May - were generally close to the long-term average; typically, in southern Britain deficits were $10-15 \mathrm{~mm}$ below the
long-term average and, commonly, $40-60 \mathrm{~mm}$ below those calculated for the same time in 1990.
From a hydrological viewpoint the build-up of modest deficits in mid-April was of considerable importance - SMDs exceeded 30 mm over wide areas of the lowlands by the end of the third week. They served to rob the substantial rainfall at the month-end of much of its effectiveness and, with little rainfall early in May, the expectation is that significant further infiltration will not occur before the autumn (see below).

## Runoff

Mean river flows in April were either above average or well within the normal range throughout most of Great Britain. Regional contrasts were however considerable and although the geological character of individual catchments exerted an obvious influence, clear evidence of an exaggeration in the normal west-to-east runoff gradient could readily be discerned - a recurring hydrological theme over the past three years.

Spate conditions were experienced in many rivers draining from the west of Scotland. The Tay (at Ballathie) and Clyde (at Daldowie) registered new maximum April runoff totals in 40-year and 28 -year records respectively. Very healthy runoff rates also typified the more maritime regions of England and Wales; typically mean flows were the highest, for April, since 1985. Hydrologically, the situation deteriorates in an easterly, or south-easterly, direction with notably depressed flow rates exhibited by rivers supported principally from groundwater in the eastern lowlands. In a few, isolated, instances the April minimum established in 1976 were superseded; examples include the River Lymn in Lincolnshire. More generally, lowland flows were often comparable with those of April 1990 and substantially greater than those of April 1976 - commonly, the April runoff totals for the drought years of 1973 and 1965 were also exceeded.

Contrasts in the geological characteristics of lowland catchments, and the prevailing soil moisture conditions, conspired to produce large local differences in response to the April rainfall. Very brisk upturns in flow rates were reported from some mainly impervious catchments in and around London at the end of the month. By contrast, the Mimram (Hertfordshire), which is dependent almost entirely on spring sources, maintained a flow rate very close to its April minimum.

The accumulated runoff totals presented in Table 3 confirm the relatively limited extent but extraordinary persistence of the 1988-91 drought. In Lincolnshire, the River Lud has remained below average since November 1988 and the 24 -month runoff total (to April) is lower than for any 24 month accumulation over the preceding record. A zone of maximum drought intensity may be traced southwards .through the central Anglian region incorporating the eastern Chilterns and extending through the lower Thames Valley into Kent. For many rivers in this zone flows have exceeded the average for four, or less, months since the summer of 1988. A remarkable measure of regional runoff variability in this timeframe may be deduced from the exceptionally abundant runoff from the Tay and Clyde catchments.

Current storage - expressed as a percentage of useable capacity - for a representative set of major reservoirs is given in Table 4. Apart from Yorkshire, stocks generally showed a further improvement during April - in marked contrast to 1990 when demand considerably exceeded the meagre replenishment and drawdowns were well established early in the spring. In the west and north, reservoir contents are close to capacity. A more uneven picture emerges in the lowlands but stocks are generally comparable with, or a little greater, than at the same time in 1990.

## Groundwater

The stuttering growth in SMDs during April, and a steadier increase in early May, is likely to signal the end of the 1990/91 recharge season at least in the lowlands. Provisional assessments of the overall winter replenishment (see Table 5) indicate that recharge to aquifers over the country as a whole have been substantial and in much of the Midlands and northern England it has been above average.

Significant increases in groundwater levels occurred through April in most areas leaving water-tables
generally approaching or exceeding the seasonal means. However, in the Chalk of East Anglia and parts of the South-East, levels remain at or near to the lowest on record (see Table 6). Even where considerable recharge has occurred over the 1990/91 winter, the very low base from which the recoveries needed to be generated has left groundwater levels well below the seasonal average.

In the Anglian region levels in the Chalk remain at, or near, the minimum recorded level for the month at the Redland Hall, Fairfields and Washpit Farm sites. The hydrograph for the latter borehole provides an excellent illustration of the combined effects of limited rainfall and sustained high SMDs on groundwater levels in an area where even in an average year recharge is very modest. At Fairfields, where the summer recession appears to have begun, the winter recovery, although indicating about $70 \%$ of the mean annual replenishment, has still left the groundwater level below the previous minimum for the spring (note, however, that the borehole record commences after the severe groundwater drought of 1973). At the Holt site, in the headwaters of the Lea system, the recovery in levels has been very moderate, and the April level, is close to the seasonal minimum. Even if it is assumed that the replenishment in these eastern districts will be of the order of $50 \%$ to $60 \%$ of the annual average, the summer recessions will be commencing at a very low level, often comparable with that recorded in 1973. It would seem possible that, by the onset of recharge in autumn 1991, the groundwater levels at some sites will be unprecedentedly low.

In the Chalk of eastern Yorkshire and of Lincolnshire, where the drought of 1990 was particularly severe, the situation is greatly improved. The winter replenishment appears to have been from $100 \%$ to $125 \%$ of the annual mean. At Dalton Holme, the groundwater level is near to the seasonal mean, and at Little Brocklesby it is now well above the seasonal minimum. In eastern Kent, the water-table at Little Bucket Farm has recovered nearly to the level reached in the spring of 1990. Westwards, a clear improvement is evident with groundwater levels generally well up towards, and sometimes above, the seasonal means.

In the Permo-Triassic sandstone aquifer, levels in the West Country continued to rise in April (see Bussels) and are now well within the normal range. A modest increase was reported for Llanfair DC borehole in North Wales but levels remain depressed. Similarly, at the Morris Dancers (Nottinghamshire) and Weeford Flats (Staffordshire) boreholes the water-table stands at its lowest since 1976/77.

In summary, although there is reason for serious concern in parts of the eastern Chalk, the country as a whole stands in better condition than might have been expected with groundwater levels near average or well above historical minima. Over large areas groundwater levels (where substantially unaffected by pumping) stand at least as high as at the beginning of the summer recession of 1990, and many areas are rather better than this. Since recharge has continued for so long into 1991, the summer recession has started equally late and, unless the onset of the 1991-92 recharge is greatly delayed, will be of relatively short duration.

Note: The recent monthly rainfall figures for England and Wales for 1991 are based upon MORECS figures supplied by the Meteorological Office. Earlier areal figures are derived from a far denser raingauge network.
Scottish RPB data for April 1991 were estimated from the isohyetal map provided with the MORECS bulletins.

Notes (i) Values based on gauged flow data unless flagged (natr.), when naturalised data have been used.
(ii) Values are ranked so that lowest runoff as rank 1;
(iii) \%LT means percentage of long term average from the start of the record to 1989. For the long periods (at the right of this table), the end date for the long term is 1990.

1. Live or useable capacity.
2. Percentage of live or useable capacity in storage at or close to the beginning of the month according to data availability.
3. Includes Haweswater, Thirlmere, Stocks and Barnacre.
4. Howden, Derwent and Ladybower,
5. Swinsty, Fewston, Thruscross and Eccup.
6. The Nidd/Barden group (Scar House, Angram, Upper Barden, Lower Barden and Chelker) plus Grimwith.
7. Lower Thames (includes Queen Mother, Wraysbury, Queen Mary, King George VI and Queen Elizabeth II) and Lee Valley (includes King George and William Girling) groups -pumped storages.
8. Farmoor 1 and 2 -- pumped storages
9. Blagdon, Chew Valley and others.
10. The new Roadford reservoir was still filling after impounding.
11. Shared between South West (river regulation for abstraction) and Wessex (direct supply).
12. Usk, Talybont, Llandegfedd (pumped storage), Taf Fechan, Taf Fawr.
13. Claerwen, Caban Coch, Pen y Garreg and Craig Goch.
