## HYDROLOGICAL SUMMARY FOR GREAT BRITAIN - JUNE 1990

Data for this review have been provided principally by the regional divisions of the National Rivers Authority in England and Wales, the River Purification Boards in Scotland and by the Meteorological Office. The recent areal rainfall figures are derived from a restricted network of raingauges and a significant proportion of the river flow data may be subject to revision following reviews of the low flow stage-discharge relations.

For a fuller appreciation of the water resources implications, this hydrological review should be considered alongside assessments of the current reservoir storage and water demand situations in each region.

## SUMMARY

As with the preceding winter and spring, the change of season heralded a relatively abrupt change in weather patterns at the end of May. In contrast to much of 1990, June was cool and cloudy. It was also a wet month in most areas, especially in Scotland where, after a brief respite, very wet conditions returned. In meteorological and agricultural terms an amelioration in drought conditions could be recognised in all regions. In England and Wales moderately severe rainfall deficiencies exist over the March-June period but regional rainfall totals since last October, and over the last year, are within the normal range. Moderate shortfalls are evident over the longer term. At the district and local scales, long term deficiencies of a substantial magnitude may still be recognised especially along parts of the eastern seaboard.

Sustained high rates of evaporation over much of Britain have contributed to a hydrological and water resources - situation which is somewhat less reassuring than the medium term rainfall figures alone might indicate. With evaporation rates and soil moisture deficits (SMDs) remaining high, the hydrological impact of the June rainfall was limited, especially in the east. Here, and in some central districts, runoff in June was exceptionally low. Elsewhere, the steep decline in monthly runoff rates since February was arrested and monthly mean flows were broadly similar to those registered in May. This interruption in the seasonal decline in flows left discharge rates significantly above the corresponding level in 1976 in most areas. Accumulated catchment runoff totals, expressed as a percentage of the average, display extreme temporal and spatial variability. Notably high values characterise parts of Scotland and major deficiencies typify catchments in eastern and southern Britain.

Some recharge was reported in western, and a few central, aquifer units but generally the seasonal decline in groundwater levels continued. Typically, water-tables stand well below average and below the corresponding levels in 1989 but substantially above the 1976 levels. In some eastern districts, however, the long-term paucity of recharge has led to severely depressed groundwater levels; many boreholes are at their lowest June level since the 1976 drought. In the absence of an inordinately wet summer no significant improvement in the groundwater situation may be expected before evaporation rates decline in the autumn.

The timing and magnitude of the recovery in runoff and recharge rates as evaporative losses decline in the autumn will largely determine the medium and longer term water resources prospects.

## RAINFALL

A sequence of low pressure systems brought widespread rainfall to all regions in June. Regional and local variations in intensity and duration were considerable. Nonetheless, rainfall totals exceeded the average in all areas apart from parts of East Anglia and central southern England where a few localities registered below $70 \%$ of the 1941-70 mean. Conversely a few districts in Scotland recorded more than twice their June average. (Table 1). ${ }^{1}$

For England and Wales as a whole and for most regions within them, the June rainfall total approached that for the preceding three months. Thus in rainfall terms and on a regional basis, the intensity of the drought which began in late-February was considerably reduced; return periods for all regions being below 50 years for the March-June period. Provisional data suggest that accumulated rainfall for England and Wales since February is still amongst the driest half dozen such sequences this century. For the Thames catchment only 1938, 1976 and, possibly, 1929 have been drier. The rainfall deficits in most areas become barely significant as the 1989/90 winter rainfalls are incorporated. Accumulations beginning in January 1990 (not shown in Table 2) and October 1989 give regional rainfall totals within the normal range. On a 12-month basis, a similar picture emerges albeit with rainfall totals for the Northumbria, Yorkshire and Anglia regions being appreciably below average. Longer term rainfall deficiencies remain significant in some eastern regions and constitute a substantial meteorological drought in a number of localities, mostly near the coast, where rain-shadow influences have been extraordinarily persistent (examples include parts of Kent, Lincolnshire, Humberside and - despite the June rainfall - some low-lying districts in the North-East).

For Scotland as a whole, May has been the only month this year with below average rainfall. The half-year total is remarkable; provisional figures indicate that the January-June rainfall is about $160 \%$ of the long-term average and is significantly greater than the 1989 total which itself was the highest in the Scottish general rainfall series (which begins in 1869). Accumulated rainfall totals for the Highland and Clyde River Purification Board areas are even more remarkable ${ }^{2}$ - see Table 2. The abundant rainfall has been accompanied by a long-term exaggeration in the west-to-east rainfall gradient. As a consequence the regional accumulations tend to obscure some large local rainfall deficiencies, notably in the North East River Purification Board Area.

## EVAPORATION AND SOIL MOISTURE DEFICTT

Temperatures and sunshine hours were below average in June. As a consequence the normal seasonal increase in potential evaporation rates and in SMDs failed to materialise. Nonetheless, the exceptionally high end-of-spring deficits registered over wide areas in May were maintained as soil moisture conditions remained relatively stable through June. Western Scotland was an exception to the general pattern; soils returned to field capacity around mid-month; some reduction in deficits also typified western hills in England. At the end of June, large parts of lowland England had computed deficiencies exceeding 100 mm and positive anomalies (relative to the end-of-June mean) of at least 40 mm were widespread.

The notably high SMDs are a consequence of the elevated evaporation rates which have obtained for many months. For example, over the October 1989-June 1990 period, record or near record PE totals (based on the MORECS data) have been registered throughout much of England and eastern Scotland. Sustained high SMDs have mitigated the actual evaporation

[^0]losses in eastern areas but, in the west, AE losses have often exceeded previous maxima in a series which commences in 1961. In the North-West, for instance, the nine-month AE total of 370 mm ( 80 mm above average) for the MORECS square embracing much of the Lune catchment exceeded the figure for the corresponding period in 1988/89 - itself unusually high. Clearly, were such elevated evaporation losses to become a regular occurrence, the water resources implications would be considerable.

The high SMDs will inhibit recharge well into the autumn; as a result of the exceptional evaporation losses - extending well over two years in some regions - the impact of relatively modest rainfall deficiencies has, in hydrological terms, been reinforced.

## RIVER FLOWS

Baseflows continued to decline through June in almost all areas. Significant, if intermittent, surface runoff provided a counterbalance however and the normal seasonal decrease in runoff totals from May to June was barely discernible in many catchments. In a few small rivers a healthy increase in runoff rates were recorded, for instance at the Cefn Brwyn gauging station on the Wye in central Wales. With the exception of much of Scotland, most flow rates remained low to exceptionally low. Significant local variations in response to the June rainfall were apparent, reflecting its intensity, the prevailing SMDs and geological contrasts between catchments. In much of lowland Britain, June runoff totals were the lowest since 1976. In some eastern, and a few central catchments (notably the Derbyshire Derwent), flows approached or fell below those recorded during the Great Drought of 1976. Generally, however, June runoff totals were several times greater than in 1976.

Accumulated runoff totals for the four months since February exhibit a remarkable spatial polarisation. Rivers draining from the Scottish Highlands have reported extremely high runoff totals - often unprecedented. Conversely in parts of lowland and eastern Britain the March-June runoff totals are amongst the lowest on record. Echoes of this contrast are present in the longer term accumulations but in England and Wales, runoff in most rivers fall within the normal range over the 6, 9 and 12 -month timeframes. Important exceptions to this generalisation may be found, particularly, in eastern rivers sustained mostly from baseflow (see for instance the Lincolnshire Lud and Yorkshire Derwent). In such catchments flow rates have been depressed for extended periods. For example, on the Derwent June was the 21st consecutive month with below average runoff; there is no precedent for such an extended period with runoff rates only half the long term average. Notably low 20 -month accumulations may also be found in a number of south-eastern rivers. The contrast with Scottish rivers which drain the western highlands is a persistent feature; runoff totals for the period commencing April 1988 are the highest on record for the Tay and the Earn. The Dee (at Park), more fully reflecting the eastern rain shadow, provides evidence for depressed flow rates for much of the last twenty months, paralleling the English conditions.

## GROUNDWATER

Although limited and localised fissure recharge was reported from a few areas, little or no significant recharge occurred throughout most major aquifer units in June. The recessions which commenced generally in late February continued. By month-end most index boreholes were recording levels in the lower quartile range for June. In eastern Yorkshire, parts of East Anglia, and eastern Kent, water-tables are especially low and may approach recorded minima by the end of the summer.

In north-western England, the Midlands and the South the heavy rainfall of February and March caused a very rapid rise in groundwater levels, in some cases approaching maximum recorded levels. However, in May and June, levels tended to fall almost equally rapidly to values which are currently below the seasonal norm. It is already realised that, where the winter rainfall is restricted in duration, it is generally more beneficial if it occurs later rather than earlier. Figure 5 illustrates this point: the 1989 and 1990 groundwater level traces for two index boreholes are
compared. The benefit of the late, albeit limited, recharge in 1989 relative to the early cessation in 1990 is clearly evident. It also now appears possible that where recharge is concentrated into a period of a few weeks, even with exceptionally heavy precipitation, the increase in resources may be more somewhat less than the recorded rise in groundwater levels suggest. It is possible that in those aquifers which, while dominantly of a fissured character, still have a significant intergranular storage, short periods of rainfall, however heavy, are insufficient to recharge the intergranular portions; consequently, the recession rate is rapid. This is because outflow from intergranular storage is not available to reinforce the fissure discharge

Groundwater levels in index boreholes are currently above, often significantly, those registered at the same time in 1976, with the exception of the Dalton Holme borehole (Humberside). The data presented in Table 4 suggest that such June levels would be expected, on average, only once in 10-20 years. Throughout much of lowland England groundwater recessions are a month or so in advance of those recorded last year. If, as happened in 1988 and 1989, the onset of significant recharge is inordinately delayed, water-tables will be very depressed towards the end of the year.

Return period assessments are based on tables provided by the Meteorological Office ${ }^{*}$. These assume a start in a specified month; return periods for a start in any month may be expected to be an order of magnitude less. "Wet" return periods underlined.
The tables reflect rainfall totals over the period 1911-70 only and the estimate assumes a sensibly stable climate.
The June 1990 RPB values are estimated from the isopleth map within the June summary published in the Met. Office's MORECS bulletin.

[^1](ii) Values are ranked so that lowest runoff as rank 1 ;
(iii) \%LT means percentage of long term average from the start of the record to 1989 . For the long periods (at the right of this table), the end date for the long term is 1990.

Note: Final estimates of rainfall provided by the Meteorological Office.

[^0]:    1 The quality control of the 1989 rainfall data has been recently completed by the Meteorological Office. For reference purposes the definitive areal figures are given in Appendix A (and have been included in this present report).
    ${ }^{2}$ In recognition of the provisional nature of the data and the uncertainties involved in the estimation procedure return periods are quoted to a maximum of 200 years only.

[^1]:    Notes (i) Values based on gauged flow data unless flagged (natr.), when naturalised data have been used.
