# Hydrological Summary for the United Kingdom 

## General

Rainfall in December was only marginally above average for the UK but, as usual in the early winter, wet soil conditions ensured that it was hydrologically effective. Correspondingly, river flows - and subsequently flood risk - increased through the month and whilst generally below average, most runoff totals were well within the normal December range. December levels in some reservoirs remained seasonally depressed (e.g. Ardingly, Lothian Region) but, aided in some areas by Drought Permits (e.g. Farmoor), some impoundments reported increases of $>25 \%$. Entering 2004, overall reservoir stocks for England and Wales were about 6\% below average, having increased by around 19\% through December - the largest single monthly increase in the 1988-2004 series. Healthy recoveries were also reported for a number of major Scottish reservoirs. Nationally, the last 10 weeks has seen a substantial moderation in drought severity but the improvement in the resources outlook has been uneven. Rainfall deficiencies increased during December in some areas (e.g. parts of Yorkshire and the South-West) and in some important aquifer outcrop areas the much-belated seasonal recoveries in groundwater levels requires above average late winter rainfall to maintain its momentum. More generally, the water resources prospects for summer 2004 will be considerably influenced by the timing of the onset of the seasonal recession in runoff and recharge rates - in this context, a wet early spring would be most beneficial.

## Rainfall

December was a very mixed bag in weather terms with frontal incursions from many points of the compass alternating with stable anticyclonic interludes. A wide range of precipitation types - from fog-drip to snow - was reported even in southern Britain. However, the very damp complexion to the weather, from mid-month especially, often failed to translate into substantial daily rainfall totals. Exceptions included 36 mm on the Isle of Wight on the 1st and 80 mm in 18 hrs at Shap Fell in the Lake District (26th) - both very useful storms in a water resources context. A few localities (e.g. Belfast) reported December rainfall totals below $70 \%$ but most catchments registered between $85 \%$ and $120 \%$ of average; the majority of regional totals were slightly above average. Despite the modest recent reduction in regional rainfall deficiencies the provisional Feb-Dec total for Britain is the third lowest since 1933. The drought remains notable in this timeframe - especially in the North-East; parts of Yorkshire recorded above average rainfall for only two months in 2003 (a distinction shared with parts of the Midlands and central southern England). After five wet years, the 2003 rainfall total for England and Wales is the lowest annual rainfall total since 1975; over the same timespan, the totals for Scotland and Northern Ireland rank lowest and second lowest respectively.

## River FIow

In most regions, river flows recovered erratically through December but, by year-end, spates were common and in some areas flood risk was increasing. However, the Naver was the only index river to register an above average December mean flow. Generally runoff totals were between $50-80 \%$ of average - mostly well within the normal range and considerable greater than drought minima (for December). The water resources stress evident over recent months is principally a reflection of the modest runoff since January 2003. This is emphasised by the runoff deficiencies for the Feb-Dec period, which for
impermeable catchments, commonly exceed $40 \%$. Index gauging stations establishing new period-of-record minima over this timespan show a wide distribution - including the Aberdeenshire Dee (in a 74-yr record), the Taw and, in Northern Ireland, the Annacloy. The importance of groundwater to river flows, in the English Lowlands especially, is emphasised by the above average runoff over the same period for a number of spring-fed streams (including the Mimram and Itchen). Baseflow contributions had generally declined greatly by early December but may be expected to recover appreciably in early 2004.

## Groundwater

The well-distributed December rainfall ensured that by month end areas with significant soil moisture deficits were restricted to a few low-lying eastern areas (e.g the Vale of York, and inland from the Wash). Elsewhere, significant but mostly below average infiltration characterised the outcrop areas of the major aquifers. A significant proportion of index wells reported too early in December to fully capture the consequent groundwater level recovery but notable rises were reported for a number of responsive aquifer units (particularly in the limestone aquifers, but in the IoW Chalk also). The upturn in the southern Chalk is especially welcome and most Chalk levels are now within the normal range - albeit still low for the early winter. Even in the normally late-responding eastern aquifer units (e.g. the Essex Chalk), and in the minor aquifers (e.g. Suffolk Crag) modest rises have been recorded. In the context of the abundant 1998-2002 recharge, the paucity of recent infiltration to the slowest responding Permo-Triassic sandstones outcrops is of limited significance - most index wells remain above average, some notably so. Near-saturated soils will ensure further significant infiltration in January but, commonly, recoveries are being generated from a very low base and the window of opportunity for further replenishment could be narrow (in the event of a dry late winter).

## Rainfall accumulation maps

The combined November and December rainfall for the UK as a whole was marginally above average - sufficient to moderate but not terminate the drought in most regions. Over the 11 -month timespan the provisional UK rainfall total is the 4th lowest in the last 100 years and substantial rainfall deficiencies persist in all regions. (Note: the resilience of water supply provision in the UK is such that only a proportion of the accumulated rainfall deficiency needs to be satisfied in order to greatly improve the water resources outlook.)

## River flow . . . River flow

## River flows - December 2003

*Comparisons based on percentage flows alone can be misleading. A given percentage flow can represent extreme drought conditions in permeable catchments where flow patterns are relatively stable but be well within the normal range in impermeable catchments where the natural variation in flows is much greater. Note: the period of record on which these percentages are based varies from station to station. Percentages may be omitted where flows are under review.

## River flow <br> River flow

## Monthly river flow hydrographs

The river flow hydrographs show the monthly mean flow (bold trace), the long term average monthly flow (dotted trace) and the maximum and minimum flow prior to 2000 (shown by the shaded areas). Monthly flows falling outside the maximum/ minimum range are indicated where the bold trace enters the shaded areas.

## Groundwater . . . Groundwater

Groundwater levels normally rise and fall with the seasons, reaching a peak in the spring following replenishment through the winter (when evaporation losses are low and soil moist). They decline through the summer and early autumn. This seasonal variation is much reduced when the aquifer is confined below overlying impermeable strata. The monthly max., min. and mean levels are displayed in a similar style to the river flow hydrographs. Note that most groundwater levels are not measured continuously - the latest recorded levels are listed overleaf.

## Groundwater. . . Groundwater

## Groundwater levels - December 2003

The rankings are based on a comparison between the average level in the featured month (but often only single readings are available) and the average level in each corresponding month on record. They need to be interpreted with caution especially when groundwater levels are changing rapidly or when comparing wells with very different periods of record. Rankings may be omitted where they are considered misleading.
(Note: Redbank is affected by groundwater abstraction. Yew Tree Farm levels are now received quarterly, Skirwith data late.)

Details of the individual reservoirs in each of the groupings listed above are available on request. The featured reservoirs may not be representative of the storage conditions across each region; this can be particularly important during droughts. The storage figures relate to the 1988-2004 period only (except for West of Scotland and Northern Ireland where data commence in the mid-1990's). In some gravity-fed reservoirs (e.g. Clywedog) stocks are kept below capacity during the winter to provide scope for flood attenuation purposes.

## Location map . . . Location map

# National Hydrological Monitoring Programme 

The National Hydrological Monitoring Programme was instigated in 1988 and is undertaken jointly by the Centre for Ecology and Hydrology Wallingford (formerly the Institute of Hydrology - IH) and the British Geological Survey (BGS). Financial support for the production of the monthly Hydrological Summaries is provided by the Department for Environment, Food and Rural Affairs (Defra), the Environment Agency (EA), the Scottish Environment Protection Agency (SEPA), the Rivers Agency (RA) in Northern Ireland, and the Office of Water Services (OFWAT).

## Data Sources

River flow and groundwater level data are provided by the Environment Agency, the Environment Agency Wales, the Scottish Environment Protection Agency and, for Northern Ireland, the Rivers Agency and the Department of the Environment (NI). In all cases the data are subject to revision following validation (flood and drought data in particular may be subject to significant revision).

Reservoir level information is provided by the Water Service Companies, the EA, Scottish Water and the Northern Ireland Water Service.

The National River Flow Archive (maintained by CEH Wallingford) and the National Groundwater Level Archive (maintained by BGS) provide the historical perspective within which to examine contemporary hydrological conditions.

## Rainfall

Most rainfall data are provided by The Met Office (see opposite). To allow better spatial differentiation the rainfall data for Britain are presented for the regional divisions of the precursor organisations of the EA and SEPA. Following the discontinuation of The Met Office's CARP system in July 1998, the areal rainfall figures have been derived using several procedures, including initial estimates based on MORECS*. Recent figures have been produced by The Met Office, National Climate Information Centre (NCIC), using a technique similar to CARP. An initiative is underway with The Met Office to provide more accurate areal figures and, since October 1999, to include more raingauges in the analysis. A significant number of additional monthly rainfall totals are currently being provided by the Environment Agencies. As with all regional figures based on limited raingauge networks the monthly tables and accumulations (and the return periods associated with them) should be regarded as a guide only.
*MORECS is the generic name for the Meteorological Office services involving the routine calculation of evaporation and soil moisture throughout Great Britain.
