## Hydrological Summary for Great Britain

## OCTOBER 1991

## Rainfall

Around $90 \%$ of average for GB but barely $50 \%$ in parts of the English lowlands. Long term rainfall deficiencies for many catchments in eastern England are remarkably large in some districts unprecedented this century.

## River flows

October runoff was below average in all regions, notably so in the English lowlands where the shrinkage of the drainage network since 1988 has been very substantial.

## Groundwater Levels

Within the average range in parts of western Britain but exceptionally depressed east of a line from the Humber to Sussex. Water-tables are at unprecedented levels in much of the Chalk and very low in the Midland sandstones.

## General

Over the majority of Great Britain, rainfall and runoff totals for 1991 thus far are within the normal range. However, the eastern lowlands of England - East Anglia especially - are afflicted by a severe and remarkably persistant drought. Reservoir stocks are healthier than in the autumn of 1990 but the current unsettled weather conditions will need to herald a wet winter if a further episode of abnormally depressed groundwater levels are to be avoided in 1992.

## HYDROLOGICAL SUMMARY FOR GREAT BRITAIN - OCTOBER 1991

#### Abstract

Data for this report have been provided principally by the regional divisions of the National Rivers Authority in England and Wales, the River Purification Boards in Scotland and by the Meteorological Office. Reservoir contents information for England and Wales has been supplied by either the Water Services Companies or the NRA. The most recent areal rainfall figures are derived from a restricted network of raingauges (particularly in Scotland) and a proportion of the river flow data is of a provisional nature.

A map (Figure 4) is provided to assist in the location of the principal monitoring sites.

## Rainfall

October was generally dull and cool with anticyclonic conditions dominating in mid-month. There was, however, considerable frontal activity early and, especially, late in the month when a very unsettled spell culminated on the 31st which (for Great Britain) was the wettest day of the year thus far.

The provisional October rainfall total for Great Britain was only a little below average but regional variations were large. In broad terms, the October rainfall pattern was consistent with that which has characterised much of the last three years over England and Wales, resulting in a marked and enduring accentuation in the normal west-to-east rainfall gradient. Much of eastern England had below average rainfall in October and the lowest percentage totals - less than half the average coincided fairly closely with the region where the drought has achieved its greatest intensity: a broad zone from Lincolnshire and the East Midlands to Kent.

Rainfall since early May has been very episodic in many areas but with only one decidedly wet month (June) accumulated rainfall totals over the last six months are below or well below average for all regions. The provisional May-October rainfall total for England and Wales is greater than the corresponding figures for 1989 and 1990 but still ranks in the driest dozen such sequences this century. More crucially in hydrological terms, the rainfall total for the three years ending in October 1991 is the lowest (for 36 -month totals beginning in November) since the 1850s. Whilst this notable nationwide deficiency provides the backcloth to the current drought much of the stress on water resources (and aquatic habitats) is attributable to the concentration of the greatest deficiencies largely in those regions where average rainfall totals are lowest. For the Thames region the rainfall total since July 1988 is comparable with the minimum 39-month accumulation in a record from 1883 and, in the Anglian region, where the drought is currently most severe, some districts have recorded above average rainfall for only two or three months since February 1990 and only around six in the last 39 months. The associated long-term deficiencies - in excess of 25 per cent for the period from August 1988 in some areas - have no parallel this century.

## Evaporation and Soil Moisture Deficits (SMDs)

Temperatures and sunshine hours were appreciably below average in most regions in October but the windy conditions helped keep potential evaporation (PE) losses close to the average. In marked contrast to the record losses registered in 1989 and 1990, PE losses for the first ten months of the year are well within the normal range. 1991 actual evaporation losses are generally also close to the 1961-88 average except in eastern England where they are among the lowest on record; towards the eastern seaboard persistently dry soils have inhibited evaporative losses for an extended period.

Soil moisture deficits currently present a very uneven picture. The relatively modest deficits in midsummer have, in the lowlands, shown only a meagre decline and in some areas SMDs continued to increase through the early autumn; however, a general, and brisk, decline began over the final week of October. At month-end, soils were wet throughout most of western and northern Britain whilst deficits exceeded 100 mm adjacent to the Thames Estuary. In this area SMDs were more than 30 mm above average and, notwithstanding significant early November rainfall, substantial deficits still characterise much of eastern England and the Midlands. Early November deficits were the equivalent of about 6 weeks average precipitation in parts of Cambridgeshire and the lower Thames Valley. This serves to emphasise the need for sustained rainfall over the remainder of 1991 to create the necessary conditions for the required substantial aquifer recharge in early 1992.

## Runoff

Except in rivers supported principally by groundwater, daily flow rates exhibited a considerable range in October. Around the 24th, notably low discharges for mid-autumn characterised most rivers. Thereafter, a strong recovery in runoff rates was evident in the west and north, especially following widespread rainfall on the 29th. At month-end some rivers reached flood alert levels in Wales and spate conditions were widespread in Scotland - the River Dee (at Park) recorded its highest flow for ten years on the 31st. In the English lowlands generally, only modest increases in flows occurred due to the moderating influence of the very dry soils.

Notwithstanding the widespread upturn in runoff rates over the final week, October runoff totals were below average in almost all index catchments (see Table 3). In western and most of northern Britain the runoff totals were, however, well within the normal range and typically much greater than in for instance - the autumns of 1975 and 1978. Flows in some upland catchments were, however, very low. The Yorkshire Derwent recorded a new minimum October runoff total in an 18 -year record and, more notably, the Dove (Derbyshire) registered an unprecedented October runoff total in a series from 1961.

Throughout much of the English lowlands monthly mean flows have remained notably stable since April and the absence, as yet, of any sustained seasonal upturn has resulted in exceptionally depressed flow rates for the third successive year. October runoff on the Trent and the Thames was the lowest since 1959 and 1947 respectively and the Little Ouse was one of an appreciable number of lowland rivers to establish new October minimum runoff totals this year. A more compelling testimony to the severity of the drought is the fact that the three lowest October runoff totals (in a record from 1968) on the Little Ouse have all been registered since 1988. Along with many rivers in a broad zone from Cleveland through much of the Midlands and East Anglia to Kent, the 95 per cent exceedance flow for the 1989-91 period is considerably lower than that for the preceding record.

The long-term decline in the baseflow contribution to streamflow continued. The Lud - a chalk stream - registered its 36th successive month with below average flows in October; over the threeyear period, the Little Ouse recorded only two months, and the Thames five months, with above average flows. For many East Anglian rivers (and some others south-east of a line from the Tyne estuary to the Bristol Channel) the long term accumulated runoff totals are the lowest, or close to the lowest on record - commonly eclipsing the modest runoff which typified the 1971-74 period in the east. The current very extended period of runoff deficiency has been accompanied by a notable shrinkage in the drainage network.

As in most years, reservoir storages changed considerably through October. In the west, reservoir contents increased significantly over the month whereas in the lowlands stocks commonly declined at least until the final week. Healthy replenishment to both gravity-fed and pumped storage reservoirs was a feature of the fortnight beginning around the 29th October; this improvement is not fully
reflected in the figures presented in Table 4. By early November storages were generally substantially greater than at the same time in 1990; this is true even in the eastern lowlands of England where the contrast between surface water resources and groundwater levels (see below) is, in some areas, stark.

## Groundwater

The expected upturn in well hydrographs anticipated after the heavy rainfall at the end of September did not materialise. Instead, groundwater levels continued to fall throughout October with minor upturns being recorded only in the West Country at the Ashton Farm and Bussels sites.

The effect of the droughts of 1989 and 1990 ensured that the summer recession of 1991 started at levels generally much below normal in eastern areas. The failure of any, other than very localised, recoveries to be generated by late-October left groundwater levels in the Chalk remaining very depressed east of a line from the Humber to Sussex. A substantial proportion of observation boreholes in this region are now recording unprecedented levels. A comparison of the autumn groundwater levels for 1990 and 1991 in eastern England provides a guide to the spatial extent of extreme groundwater drought conditions. Towards the extremities of the Chalk outcrop (as represented by the observation boreholes at Dalton Holme in the Yorkshire Wolds and Little Bucket in Kent) levels are a little above those registered last year. In between, levels in the Chalk are exceptionally depressed, the October levels are the lowest (for any month) on record at Washpit Farm (in a 40-year record), Fairfields ( 16 years) and Redlands ( 26 years).

Near to the eastern seaboard, and more extensively in East Anglia, water-tables have remained well. below average levels for much of the last three years. One measure of the remarkable persistence and severity of the drought is provided by the series of annual minima for the Dalton Holme borehole which was commissioned in 1889. A further modest decline would produce a remarkable sequence of annual minimum levels, the three lowest on record being 1990, 1989 and 1988.

In the Triassic sandstones of the Midlands, levels are reportedly very depressed in the Nottingham area and at Weeford Flats the well has dried out. To the west at the Llanfair DC site, the level on the 14th of October, although above the minimum ever recorded, is substantially below the October minimum. By way of contrast, at the more southerly sites of Ampney Crucis (in the Jurassic limestones) and Compton House (in the Chalk), groundwater levels are only slightly below the seasonal norms and the West Woodyates (Chalk) trace is marginally above the monthly average *.

With SMDs still appreciable over large parts of the eastern Chalk outcrop the drought is now entering a critical phase. Below average rainfall over the forthcoming winter would result in the spring recession beginning from an extremely low level with the likelihood that, by the autumn of 1992, water-tables would have declined appreciably below any previously experienced in a broad zone from Humberside to the Thames Estuary. Generally, around $120-150$ per cent of average winter rainfall (depending on its temporal distribution)will be required to return groundwater levels to close to the average spring peak. Although recoveries need to be generated from a very low base, groundwater level increases of the required magnitude are not especially rare - recent examples include 1974/75, 1976/77, 1978/79 and 1987/88.

Note: The most recent monthly rainfall figures for England and Wales correspond to the MORECS areal assessments derived by the Meteorological Office; for the Scottish RPBs the October 1991 totals were estimated from the isohyetal map provided with the MORECS bulletin. The regional areal rainfall figures are regularly updated (normally one or two months in arrears) using figures derived from a far denser raingauge network.

Return period assessments are based on tables provided by the Meteorological Office*. These assume a start in a specified month; return periods for a start in any month may be expected to be an order of magnitude less. "Wet" return periods underlined. The tables reflect rainfall totals over the period 1911-70 only and the estimate assumes a sensibly stable climate.

| - Live or usable capacity (unless indicated otherwise)* Gross storage/percentage of gross storage |  |  |  | $\Delta$ Percentage of live or usable capacity in storage at or close to the beginning of the month according to data availability (unless indicated otherwise) |  |  |  |  |  |  |

1. Includes Haweswater, Thirlmere, Stocks and Barnacre.
2. Cow Green, Selset, Grassholme, Balderhead, Blackton and Hury.
3. Howden, Derwent and Ladybower.
4. Swinsty, Fewston, Thruscross and Eccup.
5. The Nidd/Barden group (Scar House, Angram, Upper Barden, Lower Barden and Chelker) plus Grimwith.
6. Lower Thames (includes Queen Mother, Wraysbury, Queen Mary, King George VI and Queen Elizabeth II) and Lee Valley (includes King George and William Girling) groups - pumped storages.
7. Farmoor 1 and 2 - pumped storages.
8. Blagdon, Chew Valley and others.
9. The new Roadford reservoir was still filling after impounding.
10. Shared between South West (river regulation for abstraction) and Wessex (direct supply.
11. Usk, Talybont, Llandegfedd (pumped storage), Taf Fechan, Taf Fawr.
12. Claerwen, Caban Coch, Pen y Garreg and Craig Goch.

Note: Variations in storage depend on the balance between inputs (from catchment rainfall and any pumping) and outputs (to supply, compensation flow, HEP, amenity). There will be additional losses due to evaporation, especially in the summer months. Operational strategies for making the most efficient use of water stocks will further affect reservoir storages. Table 4 provides a link between the hydrological conditions described elsehwere in the report and the water resources situation.
