

HYDROLOGICAL SUMMARY FOR GREAT BRITAIN - NOVEMBER 1990

Data for this review have been provided principally by the regional divisions of the National Rivers Authority (NRA) in England and Wales, the River Purification Boards in Scotland (RPBs) and by the Meteorological Office. The recent areal rainfall figures are derived from a restricted network of raingauges (particularly in Scotland) and a significant proportion of the river flow data may be subject to review.

For a full appreciation of the water resources implications, the data provided in this hydrological review should be considered alongside assessments of the current reservoir storage and water demand situations in each region. Reservoir storage data, supplied by South West Water, are presented for the first time in the Hydrological Summary. It is envisaged that a more comprehensive coverage will be provided in future editions.

A map (Figure 5) is provided to assist in the location of monitoring sites.

Summary

The unsettled complexion to the weather throughout much of November failed to translate into substantial rainfall over large parts of Great Britain and an increase in the regional variations in drought intensity was evident. No notable droughts remain in Scotland at the regional scale and, notwithstanding the limited late-autumn rainfall, precipitation totals for the year thus far are very high. By contrast, in England an exceptionally severe nine-month drought may be recognised in the Thames NRA region and very notable rainfall deficiencies extend into the neighbouring regions, Anglian and Wessex especially. Medium term deficiencies (10-18 months) are generally modest but important long term deficiencies may still be identified particularly in eastern and southern England.

Generally, November river flows were well below average but remained above historical minima, except in baseflow dominated rivers in parts of the east, the Midlands and central southern England. Commonly, runoff rates were similar to those for November 1989. Accumulated runoff totals for the period beginning in April are remarkably low in a large proportion of eastern and southern Britain.

No general recovery in groundwater levels is yet evident; localised and moderate increases only have been reported. The sustained and largely uninterrupted recessions since late February, coupled with the limited recharge in many areas since the end of the 1987/88 winter, have resulted in very depressed water-tables throughout all major aquifers. Over wide areas the groundwater situation is comparable to the beginning of winter in 1989 but in the east - and in some central districts - groundwater levels have declined to absolute minima in records extending over 30 years or more.

For the third successive year, the water resources outlook at the end of the autumn is fragile over large parts of England. The soil moisture deficits (SMDs) built up through the hot and dry summer robbed this year's autumn rainfall of much of its effectiveness particularly in the lowlands. As a consequence, substantially above average rainfall will be required over the December-April period to generate increases in runoff and, especially, recharge rates of sufficient magnitude to ensure that river flows and groundwater levels are within the normal range by the spring. The very depressed levels from which a groundwater recovery will need to be generated are a matter of concern over the greater part of lowland England - aquifer recharge will need to be sustained well into the late-spring if groundwater resources are to be well placed to resist another hot, dry summer in 1991.

Rainfall

Cyclonic conditions were a common feature of the November weather but they did not exhibit the vigour which may be expected towards the end of the year. In central southern and parts of northern Britain rainfall tended to be in the form of light showers or intermittent episodes of drizzle rather than the sustained frontal rainfall which, on average, makes November one of the wettest, if not the wettest, months of the year.

Frontal activity in and around the North Sea made an exception of some eastern coastal areas south of the Humber, where the November rainfall total was significantly above average. Elsewhere, rainfall was appreciably below the 1941-70 mean - a few districts, mostly in the Thames Valley and parts of Wessex, received less than 40% of average; much of northern Britain was also relatively dry. Autumn (September-November) rainfall totals are generally below the average but within the normal range in all regions. The persistence of substantial longer term deficiencies testify to the remarkable dryness of the spring (especially) and the summer.

For England and Wales as a whole the provisional March to November rainfall total was the lowest in the entire general rainfall series (beginning in 1766) with the exception of 1921. For the Thames Valley, the nine-month accumulation is even more extreme; each of the individual monthly rainfall totals was below average and the March-November catchment rainfall total is the lowest on record by a considerable margin - the 1921 total is the only one to come within 100 mm of the 281 mm (provisional) registered this year. Considering *any* nine-month period there are only five drier sequences (three of which occurred during the 1975/76 drought) in the 107-year record. The Institute of Hydrology's raingauge (at Wallingford) was one of a number in central southern England recording less than half the average rainfall over the March-November period. Table 2 emphasises the regional nature of the meteorological drought in this timeframe. The extraordinary transformation in weather patterns around the end of the 1989/90 winter is reflected in the very modest return periods for the rainfall over the last 12 months. For the Thames, Southern, Wessex and South-West NRA regions winter (December-February) precipitation exceeds that for the ensuing nine-months; a remarkable temporal contrast given the normal, fairly even, rainfall distribution throughout Great Britain.

In addition to those regions where the 1990 rainfall deficiency is currently most acute, longer term droughts may also be recognised along the eastern seaboard and across southern England. Where these droughts incorporate below average rainfall in the winters of 1988/89 and 1989/90 - for instance in parts of Yorkshire, Humberside, Lincolnshire, East Anglia and Kent, the effect on groundwater resources has been severe (see below).

Evaporation and Soil Moisture Deficits

Although less remarkable than many recent months, sunshine hours and temperatures were still a little above average throughout the greater part of the UK in November. Correspondingly evaporation rates were greater than normal and PE losses this year appear likely to match or exceed the records established in 1989. The AE picture is more complex with evaporation losses being inhibited by the large SMDs prevalent since April.

By the end of November soils were at, or close to, field capacity throughout much of northern and western Britain. Towards the English lowlands a sharp transition takes place with large deficits (notably so relative to the long term average) typifying much of central England and parts of the north-eastern lowlands. Very high deficits - in excess of 80 mm - characterise parts of the Thames Valley; long term records indicate that the late-November SMDs in some districts are unprecedented over a 70-year period - spatial variability is considerable also. Along England's south-eastern coastline, the November rainfall was noticeably beneficial and in Norfolk and Suffolk late-autumn SMDs were close to the long term average. Except in such eastern districts, end of November SMDs were generally a little lower than those of 1989 but exceptions could be seen in the drier soils of the Cotswolds, parts of Wessex and central southern England.

In terms of the water resources outlook it is important that the remaining SMDs be smartly

reduced so that the aquifer recharge period, especially in eastern districts, is not severely restricted over the 1990/91 winter - recharge may be expected to cease as evaporation rates climb through the spring.

Runoff

Notwithstanding the declining evaporative losses, the seasonal recoveries in river flows evident in October - at least in impermeable catchments - were not reinforced in November, apart from rivers in the South-West and in a few other catchments. Runoff totals for the month were well below average throughout almost all of Great Britain with many eastern and southern catchments recording less than half the long term average. In the more maritime regions runoff totals, whilst modest, were substantially greater than in other recent autumn droughts (e.g. those of 1983, 1978, 1975 and 1972) and, over wide areas, were broadly comparable with 1989. On the other hand, many baseflow dominated rivers in the English lowlands - and some other areas, notably the Yorkshire Wolds and North York Moors - remain at very depressed flow rates. Using the November mean flows as a yardstick, the 1990 hydrological drought is most severe in the Thames NRA region. Runoff in November was the lowest in a 28-year record for the Coln which drains the dip-slope of the Cotswolds. The Thames at Kingston registered its lowest naturalised mean flow (for November) since 1947. Exceptionally low flows were also recorded on the Kennet and the Mimram and on other Chalk rivers beyond the Thames Valley - the Itchen (Hampshire) and Lud (Lincolnshire) being notable examples.

With the exception of rivers in the the Thames and Wessex NRA regions, return periods associated with the November flow rates are generally less than twenty years or so; in part this is a reflection of the moderating influence of the very low runoff totals for November 1988 and 1989 upon the flow frequency analyses.

Accumulated runoff totals remain very depressed throughout the major part of Great Britain. Over the autumn (September-November) mean flows have been especially low in the Wessex, Southern, Anglian and - particularly - the Thames NRA regions; very modest totals also characterise a number of predominantly permeable catchments to the north of the Humber. The most meaningful indices of current drought severity are probably the runoff accumulations since April (Table 3). Many lowland rivers have recorded below average flows in each of the eight months and accumulated deficiencies of greater than 50% are common. The eight-month runoff total for the Thames is the lowest since the 1934 drought (this is true also of each of the 3 to 7-month accumulations ending in November). Return periods in excess of 20 years (for the eight-month accumulations) also characterise a number of rivers with limited baseflow support in lowland Britain and a few less responsive southern and eastern rivers (e.g. in parts of the Yorkshire NRA region).

The effect of the abundant runoff over the 1989/90 winter (December-February) is evident from the 12-month runoff totals listed in Table 3; those with accumulations less than about 70% of the LTA help identify the regions of maximum hydrological stress - parts of Yorkshire, Humberside, East Anglia and large parts of central and southern England. The transformation in runoff conditions through 1990 has no recent parallel but on the Thames (for instance) the overall recession in 1947 - from a notable monthly peak in March - embraced a significantly wider flow range than has been experienced this year.

From mid-October runoff to gravity-fed impoundments in the west has produced a healthy measure of replenishment - see, for example, Figure 3. Elsewhere improvements in reservoir stocks have been generally marginal. In Wessex, for instance, overall storage is appreciably less than at the end of the 1989 drought.

Groundwater

The recession of groundwater levels has continued through November with little if any significant recharge. Even away from the eastern seaboard, upturns (at the BGS index sites) have been observed only in one Carboniferous Limestone well and in a few observation boreholes along the

south coast and in the far south-west. Modest increases have also been reported for parts of Wessex and Kent but generally water-tables remain exceptionally low throughout all major aquifers.

The limited rainfall in November has caused an increase in drought severity as indexed by the groundwater levels in nationally monitored wells and boreholes. The data in Table 4 show that, at seven of the index sites listed, groundwater levels are below the minimum recorded November levels, while at five sites the levels are the lowest ever recorded. At the Dalton Holme site (in the Chalk of the Yorkshire Wolds) groundwater levels continue to decline below the previous minimum (in a 101-year record) and now stand about 4.5 metres below the end-of-autumn mean level; a rise of nine metres would be required to bring levels back to the monthly average by March.

Gentle recessions through into early December have left water-tables over large parts of England at an unprecedented level, albeit often only a little below the corresponding levels in 1989. In parts of Yorkshire, Humberside, Lincolnshire, East Anglia and southern England, groundwater levels have fallen below the minima established at the end of the 1976 drought. A particularly dramatic decline in levels through the autumn was registered at the Ampney Crucis site (in the Middle Jurassic Limestones); levels remained below the preceding minimum throughout November and the magnitude of the fall since late-February has no close precedent in a 32-year record.

With groundwater levels over wide areas below the early-winter average by amounts greater than the mean annual fluctuation, the prospects of restoring water-tables to the normal spring level are poor. In excess of 150% of average precipitation over the winter and early spring will be required in some southern and eastern areas. The temporal distribution will also be important - the benefits of even exceptionally heavy winter rainfall will be considerably diminished if, as in 1990, a very dry episode in March/April produces an early, and steep, resumption in water-table recessions.

Return period assessments are based on tables provided by the Meteorological Office*. These assume a start in a specified month; return periods for a start in any month may be expected to be an order of magnitude less.

The tables reflect rainfall totals over the period 1911-70 only and the estimate assumes a sensibly stable climate.

Notes (i) Values based on gauged flow data unless flagged (natr.), when naturalised data have been used.
(ii) Values are ranked so that lowest runoff as rank 1;
(iii) %LT means percentage of long term average from the start of the record to 1989. For the long periods (at the right of this table), the end date for the long term is 1990.
