## HYDROLOGICAL SUMMARY FOR GREAT BRITAIN MARCH 1990

Data for this review have been provided principally by the regional divisions of the National Rivers Authority in England and Wales, the River Purification Boards in Scotland and by the Meteorological Office. The recent areal rainfall figures are derived from a restricted network of raingauges and a significant proportion of the river flow data is of a provisional nature.

For a fuller appreciation of the water resources implications, this hydrological review should be considered alongside assessments of the current reservoir storage and water demand situations in each region.

#### Abstract

SUMMARY March was a warm, dry month throughout most of Great Britain. Generally, river flows and groundwater levels declined steeply following the remarkable hydrological conditions experienced in February and significant soil moisture deficits developed in most lowland regions. On a regional basis, monthly runoff totals and groundwater levels in March were within the normal range for the spring. However, spatial variations were considerable and the water resources situation is very much healthier in the west than in parts of the eastern lowlands where rain-shadow influences have been very persistent. As a consequence, runoff and recharge rates which are modest even in a typical year - have been below average in a few areas for the second successive winter and the resources outlook remains fragile.

## RAINFALL

March was yet another month dominated by south-westerly winds. Unlike the mid-December to mid-February period however, the great majority of low pressure systems followed a northerly track remote from southern Britain. Rainfall was abundant only in Scotland where some extraordinary precipitation totals have been registered throughout the winter period. Much of eastern and southern Britain recorded less than half the average March rainfall and a few localities, for instance in east Kent, registered as little as 2 mm over the entire month.

For England and Wales as a whole provisional data indicate that March was the driest month for four years and had the fifth lowest March rainfall total this century. In many parts of lowland Britain a significant dry spell had extended to eight weeks by the second week of April.

The recent dry episode served to only partly counterbalance the exceptionally wet interlude which preceded it. Winter half-year rainfall totals are very close to, or above, average for all regions. The six-month precipitation total for Great Britain is 20 per cent above the 1941-70 mean and might be expected, on average, about once every ten years. Such frequency estimates - especially when based on standard tables derived using data up to 1970 only - need to be treated with caution in view of the exceptional clustering of wet winters in recent years. This is especially true of Scotland where the 1989/90 October-March rainfall total of 1004 mm ranks as the 3rd highest (after 1982 and 1988) on record. More remarkably, eight of the twelve wettest winters in a series extending back to 1869 have occurred over the last decade - for this period rainfall in Scotland is $20 \%$ greater than the 1941-70 mean.

Winter rainfall totals were far less extreme in England and Wales but the transformation in hydrological conditions over the period early-December to mid-February served to effectively terminate the drought in western and central areas. October-March rainfall totals, relative to the average, are lowest in eastern districts where significant local variability in rainfall patterns has also been evident. Not all long-term rainfall deficiencies have been eliminated and in the 17 -month time-frame a substantial shortfall may still be recognised in Northumbria with significant deficiencies in parts of Yorkshire and the Southern NRA region. These deficiencies constitute a continuing severe meteorological drought in a few localities along the eastern seaboard of Britain.

## EVAPORATION AND SOIL MOISTURE DEFICITS

The exceptionally mild conditions in March were conducive to relatively high rates of evaporation and, as a result, soil moisture deficits - which were non-existent in all but a few localities throughout most of February - began to build in March. By month-end, SMDs were significantly above average in central, southern and eastern England; this limits the potential for further aquifer recharge during the remainder of the spring.

Computed actual evaporation losses in 1990 have been between $30 \%$ and $40 \%$ above average over large areas of Britain. Normally January-March evaporation totals are very modest, typically $10-15 \%$ of the annual total. Any tendency for this proportion to increase will have significant water resources implications. Fortunately, over the full 1989/90 winter half-year the very truncated period during which soils were at field capacity - at least in southern and eastern Britain - resulted in actual evaporation falling somewhat short of the potential figure in the late autumn and early winter, thereby partially counteracting the impact of the subsequently high evaporation losses.

## RIVER FLOWS

The meagre rainfall and unusually high evaporation rate led to a brisk decline in river discharges through March. Spatial variations in runoff rates were also considerable with catchment geology exercising a powerful influence on river flow patterns.

Although recessions became established in Scotland during late February most rivers remained in spate throughout much of March; both the Tay and Clyde established new record runoff totals for the month. By contrast, rivers draining impervious catchments in southern Britain exhibited steep recessions resulting in daily flow rates substantially below the spring average by early April. The monthly runoff in March for rivers such as the Medway (Kent) and the Mole (Surrey) has a return period of the order of 5-10 years. Modest runoff totals also characterise a number of eastern rivers sustained principally from baseflow - the Derwent (Yorkshire) and Lud (Lincolnshire) are examples. For such catchments the accumulated runoff total over periods extending up to $18-24$ months are among the lowest on record. Typically, the combined winter half-year runoff for 1988/89 and 1989/90 is the lowest, for two successive winters, since the early 1970s; for the Derwent, winter runoff since October 1988 is unprecedented. Away from the eastern lowlands, long-term runoff totals are healthy especially over the six-month winter period and continuing substantial baseflow support (a consequence of the heavy recharge in early 1990) is evident in many central and southern catchments.

The abundant reservoir replenishment in virtually all areas during January and February implies that the water supply outlook is considerably more encouraging than the end-of-March river flows might, in isolation, imply. Certainly most regions are considerably better placed to withstand a summer drought than at the corresponding time in 1989. However, a continuation of the current recessions into the late spring could present difficulties in some eastern rivers particularly if spray irrigation demands increase steeply.

## GROUNDWATER

Infiltration during March was greatly below average throughout most major aquifers. Nonetheless, groundwater levels stood within the normal range in most index boreholes. The extreme regional contrasts apparent during late February have been moderated. Steep declines in water levels have been recorded in many western and central aquifer units whilst belated responses to earlier infiltration have occurred in deeper boreholes in eastern areas where the recoveries are being generated from a very low base. Some further modest recoveries may be anticipated where a lengthy lag exists between rainfall and water table response but little further infiltration may now be expected before the autumn.

Groundwater levels at the beginning of the 1989-90 winter were inordinately low, particularly in some eastern and southern aquifers. A belated seasonal upturn generally began over the latter
part of December. However, apart from some western areas, groundwater levels were still well below average at the end of the year. During January, further heavy rainfall led to continued infiltration and consequent rises in groundwater level in the south-west and south of England, but the effects appear to have been much less marked in the extreme south-east, the north Midlands and the north-east. During February a remarkable increase in infiltration led to substantial rises in groundwater level as shown in the well hydrographs in Figure 3, (locations are shown in Figure 4). By the beginning of March 1990, the winter recharge had generally exceeded the mean values (Table 4), while groundwater levels stood at, or above, the seasonal means. Exceptions appeared to be in the Chalk of Yorkshire and in Kent where the groundwater levels remain considerably below the seasonal mean.

The unusually low rainfall of March inevitably led to a sharp decrease in infiltration. By the last week of March, groundwater levels were still rising at Little Bucket Farm, at Washpit Farm and at Dalton Holme; this is probably, at least in part, due to the prolonged lag between rainfall and consequent groundwater level recovery caused by the unusually depressed levels of the 1989-90 winter. Elsewhere, the rise in groundwater levels had levelled off, as at the New Red Lion site, or were falling. Unless unusually heavy rainfall is experienced during April, these downturns signal the commencement of the summer recessions.

Table 4 shows the percentage of the mean annual recharge as measured at seven indicator well sites. At those sites where the downturn in groundwater levels has already taken place, the $1989-90$ recharge is within the range $100 \%$ to $150 \%$. Recharge so far for the Little Bucket borehole in Kent is over $90 \%$ (but see below) however, as a consequence of the historically exceptional levels registered early in the winter, groundwater levels remain significantly below the spring average. In East Anglia (Washpit Farm) and Yorkshire (Dalton Holme), the recharge to the end of the month was $34 \%$ and $44 \%$ respectively; it is thought that for these districts, the $1989-90$ recharge is unlikely to exceed at best $60 \%$ to $70 \%$ of the annual mean.

The overall picture is reassuring, and groundwater resources over most of the country are above, in some areas well above, the seasonal average. Although groundwater levels in parts of East Anglia and Yorkshire are still well below the seasonal mean, the situation is much less serious than had been suggested by the lack of recharge through the autumn and early winter. The network of index boreholes provides a broadly representative picture of aquifer storage in England. In some areas, however, local variations in recharge rates through the winter have been important and in several localities, parts of north Kent especially, little or no recovery in groundwater levels has yet been reported and the water supply outlook is a matter of concern.

## ERRATA

Certain of the rainfall figures for Scotland given in the February Hydrological Summary were erroneous. Correct values are given in Table 1 and the corresponding return period assessments are quoted below.
Rainfall in Scotland Feb 1990 Jan 90-Feb 90 Dec 89-Feb 90

[^1](ii) Values are ranked so that lowest runoff as rank 1 ;
(iii) OLT means percentage of long term average from the start of the record to 1988 . For the long periods (at the right of this table), the end date for the long term is 1990.

Site nome, ROCKLEY
Nationol grid reference, SU 16557174 Well number, SU17/57
Aquifer: CHALK AND UPPER GREENSAND Meosuring level, 146.39

1986
1987
1988
1989
1990

Max, Min and Mean values calculated From years 1933 TO 1989

SIte nome, LITTLE BUCKET FARM, WAL THAM
Notional grid reference, TR 12254690
Aquifer, CHALK AND UPPER GREENSAND

> Well number, TR14/9

Max, MIn and Mean values calculated from years 1971 T0 1989

site name, DALTON HOLME
Notional grid reference, SE 96514530 Well number, SE94/5
Aquifer, CHALK AND UPPER GREENSAND Measuring level, 33.50

Max. Min and Mean values calculated From years 1889 TO 1989

Site name: AMPNEY CRUCIS
National grid reference, SP 05950190 Well number: SP00/62
Aquifer: MIDDLE JURASSIC Measuring level, 109.70

Site nome: NEW RED LION
Notional grid reference, TF 08853034
Hell number: TF03/37
Aquifer, LINCOLNSHIRE LIMESTONE
Measuring level, $\quad 33.82$

TABLE
RISE IN GROUNDWATER LEVELS AT CERTAIN INDICATOR WELL SITES FOR THE WINTER OF 1989-90, AND THE CALCULATED PERCENTAGE OF MEAN ANNUAL RECHARGE SO FAR RECEIVED.

| Site | Latest date of <br> measurement | Approximate rise <br> in groundwater <br> levels (metres) | Mean annual <br> range (metres) | Percentage of mean <br> annual recharge |
| :--- | :---: | :---: | :---: | :---: |
|  |  |  |  |  |
| Compton House | 020490 | 31.8 | 21.8 | 146 |
| Rockley | 040490 | 14.6 | 10.9 | 134 |
| Little Bucket Farm | 020490 | $10.4 *$ | 11.4 | 91 |
| Washpit Farm | 040490 | $1.0 *$ | 2.9 | 34 |
| Dalton Holme | 090490 | $3.7 *$ | 3.1 | 132 |
| Ampney Crucis | 020490 | 41 | 9.2 | 101 |
| New Red Lion | 270390 | 9.3 |  |  |

For sites marked by *, groundwater levels were still rising at the latest date of measurement.

[^0]:    Return period assessments are based on tables provided by the Meteorological Office ${ }^{*}$. These assume a start in a specified month; return periods for a start in any month may be expected to be an order of magnitude less.
    The tables reflect rainfall totals over the period 1911-70 only and the estimate assumes a sensibly stable climate.
    The March 1990 RPB values are estimated from the isopleth map within the March summary published in the Met. Office's MORECS bulletin.

    * Tabony, R C, 1977, The Variability of long duration rainfall over Great Britain, Scientific Paper No. 37, Meteorological Office (HMSO).

[^1]:    Notes (i) Values based on gauged flow data unless flagged (natr.), when naturalised data have been used.
