## HYDROLOGICAL SUMMARY FOR ENGLAND AND WALES - AUGUST 1989

Data for this review have been provided, principally, by the regional divisions of the National Rivers Authority and by the Meteorological Office.

The rainfall figures are derived from a restricted network of raingauges and some of the flow data are of a provisional nature. A significant proportion of the featured hydrometric data may thus be subject to later revision.

For a fuller appreciation of the water resources impact of the current drought, this hydrological review should be considered alongside assessments of the current reservoir storage and water demand situations in each region.

## Summary

The synoptic conditions during August were generally similar to those that have determined weather patterns over Great Britain for much of the last 16 month period. Low pressure systems tended to skirt the western seaboard bringing abundant rainfall to western Scotland and parts of north west England. Few active depressions penetrated to southern and eastern areas where - as a consequence - the drought has increased in intensity. Over the period since late-April a severe drought has developed in large parts of southern Great Britain and substantial longer term rainfall deficits exist over a large proportion of lowland England and in Northumbria. These deficits are particularly notable in the Southern NRA region and are of a significantly lesser magnitude in parts of East Anglia. Except in a few locations, and over selected periods, the drought severity - in hydrological terms - does not approach that of 1976.

River flows throughout most of England and Wales are well below average and in many catchments similar to those registered towards the end of the 1984 drought. Typically the August 1989 runoff totals might be expected once every five to ten years. Somewhat longer return periods are associated with runoff rates in some relatively impervious southern catchments - especially in the South West - and also in a few chalk or limestone catchments where baseflows have declined considerably in response to the very limited infiltration since early 1988.

No significant recharge to major aquifers normally occurs in the late summer and groundwater levels have continued their seasonal recession. Water tables are generally well below average but significantly above historical minima partly as a consequence of the beneficial (albeit limited) late infiltration in the spring.

Both the 1976 and 1984 droughts were terminated by heavy and sustained autumn rainfall. The magnitude and impact of the 1989 event, and the water resources prospects for 1990 , will be heavily influenced by precipitation amounts over the next three months. Considerable rainfall will be required to satisfy the large soil moisture deficits and generate the normal seasonal upturn in runoff and recharge rates.

## Review

The passage of several frontal systems - especially around the 10th and the 25th - brought widespread rainfall, heavy in places, to most areas of England and Wales. However these wet interludes failed to greatly disturb what has become a familiar pattern during the current drought. August rainfall totals north-west of a line roughly from Dyfed to Cleveland were generally above average. Elsewhere, few areas exceeded 75 per cent of the mean and less than half the average rainfall was received in some eastern and southern districts.

Many ares of England and Wales have recorded below average precipitation for all but five of the last 17 months (see Figure 1). Although below average, summer (June-August) rainfall over England and Wales was unexceptional being about twice the corresponding figure for 1976 and also greater than in 1975, 1981, 1983 and 1984. However, a different picture emerges if May is included. The four-month period ending in August is the second driest this century (after 1976) and in some districts the associated return period is in excess of 100 years. The regional variations in intensity may be judged by reference to Tables 1 and 2. With the exception of the North West, substantial deficits exist in all regions for the ten-month period beginning in November 1988.

Although on the four-month timescale there are certain affinities with the 1976 drought any general comparisons remain inappropriate. The 'Great Drought' has no modern parallel in terms of its duration and severity. Relative to average rainfall, the percentage shortfalls for durations in the two to eighteen month range (see Figure 2) serve to illustrate both the important temporal variations in the severity of the 1988/89 drought and its lesser magnitude compared to the extreme conditions experienced in 1975/76. In the current event, for England and Wales as a whole, no durations exceed a 50 year return period; in 1975/76 return periods associated with almost all durations were well in excess of 200 years. The 1988/89 profile for the South West NRA region confirms the intense nature of the drought over the May-August period; the associated return period being about 100 years. The development of the 1988/89 winter drought is also evident together with the important amelioration which took place is the spring. For the Southern NRA region the $1988 / 89$ drought profile shows the characteristic two phases (winter and summer) but reveals also a substantial rainfall deficit over durations from 12-18 months.

Mean temperatures and sunshine hours were above average in August and open water evaporation losses were high. However, with soils already exceptionally dry the potential for further increases in soil moisture deficits was small. In contrast to some parts of western Scotland, where a return to field capacity occurred in August, calculated SMDs for most areas of England and Wales were above 100 mms at the month's end; in southern England deficits of 125 mm were typical. A few localities in North Wales and the North West registered below average end-of-summer SMDs but, in the south, they exceeded the seasonal mean by $20-80 \mathrm{~mm}$ and were, over wide areas, similar to the deficits obtaining towards the end of the 1984 drought. Such deficits are equivalent to about two months of average autumn rainfall and will clearly delay the onset of aquifer recharge and any substantial upturn in runoff rates.

River flows continued their seasonal decline in almost all parts of England and Wales and catchment runoff totals for August were substantially below average, markedly so in parts of the South (see Table 3 and Figure 3). However, in much of the English lowlands the benefit - in terms of baseflow support - of the belated spring recharge is still evident with flow rates in most catchments considerably above historical minima. Broadly speaking, flows have declined to rates expected about once every $5-10$ years (on average) and are similar to those recorded in August 1984. Somewhat more extreme flows characterise areas like the South West and South Wales where only limited natural storage exists to sustain flows through drought periods. For instance the River Cynon (South Wales) recorded an August mean flow approaching the 1976 minimum and the Kenwyn (Cornwall) - which does have an appreciable baseflow - also registered an August mean with a return period in the 15-20 year range. Notably low flows were also recorded in some rivers draining predominately pervious catchments where baseflows have been depressed for over a year. The Yorkshire Derwent and the Hampshire Itchen fall into this category. Flows in the latter, when adjusted to account for the recently increased augmentation from groundwater, are comparable to those recorded in 1976 and correspond to about a 40-50 year return period. The Thames which drains a geologically diverse catchment registered its third lowest August runoff since 1949 nonetheless naturalised flow rates were still twice those recorded in August 1976. The accumulated runoff totals presented in Table 3 further emphasise the broad extent of the drought, its uneven geographical impact and, in most regions, its moderate severity relative to the 1976 event.

Whilst in most catchments, August runoff compared favourably with corresponding totals in 1976 and 1984 a continuation of dry, or even average, conditions into the autumn will certainly see 1989 flows fall below those experienced in 1976 and 1984 when heavy September rainfall paved the way for a subsequently brisk increase in discharge rates.

Whilst groundwater levels through the late winter and early spring of 1989 were the lowest since 1976 over wide areas, the subsequent infiltration, although limited compared with winter recharge in a normal year, boosted groundwater resources at a time when a seasonal decline in levels is generally under way. Consequently, in early summer, water tables stood at around average levels in some regions (see, for instance, the Compton and Rockley traces - Figure 4), although most observation boreholes showed levels somewhat below the average for June. However, only in parts of the Chalk aquifer in Sussex, Kent and Yorkshire were levels reported comparable with those registered in June 1976; increased abstraction rates as well as the meteorological conditions are an important factor in some of these localities.

Infiltration appears, generally, to have ceased by June, and groundwater hydrographs are now, typically, showing a normal summer recession. The set of groundwater level hydrographs appended to this report illustrate that even where the $1988-89$ recharge has been very modest, at Dalton Holme for example, groundwater levels remain above, and in general considerably above, the minimum on record. No significant recharge to major aquifers is likely before October, when rainfall may normally be expected to exceed evaporation losses.

Groundwater shortages, other than those of a localised nature, may be anticipated only if, as happened in 1988, autumn and early winter rainfall is inadequate to allow normal recharge to produce a substantial upturn in groundwater levels.
