Data for this review have been provided, principally, by the Regional Units of the National Rivers Authority and by the Meteorological Office.

A proportion of the data featured is of a provisional nature and subject to later revision. In particular, the areal rainfall totals derive from a limited raingauge network and, given the substantial spatial variability in the June precipitation, the figures tabulated in this report should be treated with caution.

## SUMMARY

During much of June, hot and dry conditions prevailed throughout most of England and Wales. Evaporation losses, especially in mid-month, were high and soil moisture deficits climbed steeply. As a consequence, and following a remarkably dry May, the general perception was of an intensifying drought. In fact, weather was very unsettled both at the beginning and at the end of June. The associated rainfall was substantial in many areas and, overall, June rainfall was close to the average for England and Wales as a whole.

River flows declined more gently than in May, but over wide areas, June runoff totals were the lowest for June since 1976. However, apart from some southern districts, discharge rates remain several times greater than the corresponding flows in 1976 and, typically, the June flows are associated with return periods in the $5-10$ year range. Normally minimal infiltration to major aquifers occurs normally in June, currently, the groundwater situation remains fairly stable with levels below average but, in most regions, substantially above those registered during historic droughts. Summer rainfall has only a minor influence on water resources and the longer tern impact of the 1989 drought will be largely determined by precipitation amounts from September onwards when replenishment of reservoirs and recharge to aquifers would normally be expected to re-commence.

## REVIEW

A sequence of moderate low pressure systenis - on a northerly airstream brought widespread showery conditions to much of the UK over the period 1-8th June; thundery showers were widespread and accompanied by significant - if locally very variable - rainfall. Pressure then rose and an anticyclonic weather pattern became established. Apart from a brief interlude on the 20/21st, dry and very hot weather characterised almost all regions until the rainless spell - which extended to 18 days in some localities - was terminated by sustained rainfall associated with an active cold front on the 28 th . This heralded a series of depressions bringing significant rainfall to all regions; precipitation totals were modest, however, in South Wales and the South West. In these latter areas the monthly rainfall, in parts, was less than half the average; by contrast parts of the North Downs, East Anglia, Yorkshire and coastal districts of Lancashire exceeded 150 per cent.

The rainfall deficit over the ten-week period ending in late June was significant in most regions but the combined total for May and June is not remarkable; a return period of about five years being typical. Over the nine nonths to the end of June a more notable drought may be recognised, albeit one with two distinct phases separated by a wet interlude in the spring (see Table 1). Overall, the greatest rainfall deficits continue to be found in the Southern Water area where a significant shortfall may be traced back to April 1988 - a return period of approximately 20 years is associated with this deficit and in some districts a drought of greater
severity may be recognised. However, except in a few localities, comparisons with 1975/76 are clearly inappropriate; this latter event was of an extreme severity recording approximately 130-170 min less rainfall in those water authority areas where the current drought has achieved its greatest intensity.

Mean temperatures and sunshine amounts were significantly above average in June and potential evaporation totals - especially in mid-month - were very high. Soil moisture deficits increased sharply over this period and even though some stabilisation occurred at the month's end, SMDs entering July were greater than 100 mm throughout most of England and Wales south of the Wash. Relative to the late June average, 1989 deficits were generally 50 mm greater and, apart from eastern coastal districts, substantially exceed those normally obtaining at the end of the summer.

June river flows throughout England and Wales were generally in the range 30 to 90 per cent of the average (see Table 2) with clear regional patterns difficult to discern; partly this reflects the variation in the June rainfall and the contrasting geological character of individual catchments. Broadly speaking western and northern areas - parts of Yorkshire and Lancashire excepted - continued the steep recessions that became established in late April. A few rivers in South Wales recorded June flows lower (marginally) than in 1976. More generally, flows tended to be the lowest recorded since the late summer of 1984 and, typically, may be expected once every 5-10 years or so. Less spatial coherence may be identified in the English lowlands. A few rivers, including the Mole in Surrey, recorded above average June flows; a response to abundant rainfall on the North Downs and the continuing benefit to baseflows deriving from the late recharge over the March to May period. More typically, June runoff totals were the lowest - for the month - since 1976 but often exceeded the corresponding flows in 1988 by only a modest margin. Apart from rivers in the Southern Water area - where return periods of twenty years or more have been estimated - discharge rates are generally well below average but significantly greater than those registered during major historical droughts. Flows in the Thames, for instance are three times those recorded in 1976 and considerably greater than the June mean flow recorded in the droughts of 1899, 1921, 1933, 1944 and 1949. The accumulated runoff totals (since October 1988) given in Table 2 testify to a significant rather than severe hydrological drought in all but a few catchments.

Whilst groundwater levels through the late winter and early spring of 1989 were the lowest since 1976 over wide areas, the subsequent infiltration, though limited in comparison with winter recharge in a normal year, boosted groundwater resources at a time when a seasonal decline in levels is generally underway. Consequently, in early summer, water tables stood at around average levels in some regions (see, for instance, the Compton and Rockley traces) though most observation boreholes stood somewhat below the June average. However, only in parts of the Chalk aquifer in Sussex and Kent and the Permian Sandstones of east Devon were levels reported comparable with those registered in June 1976; increased abstraction rates as well as the meteorological conditions are an important factor in some of these localities.

Infiltration appears, generally, to have ceased by June and groundwater hydrographs - except those for deep wells which respond to rainfall only after a lag of several months - are now, typically, showing a normal summer recession. The set of groundwater level hydrographs illustrate that even where 1989 recharge has been very modest, at Dalton Holme for example, groundwater levels remain considerably above the minimum on record. No significant recharge to the major aquifers is likely to occur before October - when rainfall may be expected to exceed evaporative losses. Groundwater shortages - other than those of a localised nature -
may be anticipated only if, as happened in 1988, autumn and early winter rainfall is inadequate to allow normal recharge to produce a substantial upturn in groundwater levels.
