Data for this April review have been provided, principally, by the Water Authorities and the Meteorological Office.

A substantial proportion of the recent data featured in this note is of a provisional nature and subject to later revision.

#### Abstract

Summary April was a wet month, notably so in some areas, and the water resources situation continued the improvement which began in mid-February. Soils remained close to field capacity throughout April and runoff and aquifer recharge totals were substantially greater than the monthly average over wide areas. Whilst total 1988/89 replenishment of the principal aquifers remains below normal, the late surge in infiltration over the last 8-10 weeks is especially beneficial - levels in most index boreholes are expected to be close to the average by mid-May and the outlook for baseflow supported rivers is reassuring.

## Review

In contrast with much of the preceding winter, April was cold and wet. A sequence of frontal systems brought unsettled conditions and several episodes of prolonged steady rainfall. Rainfall totals a little below average were recorded in South Wales and along the north-east coast but elsewhere precipitation was abundant; substantial areas of central England had more than twice the April mean and, generally, rainfall over the outcrop areas of the major aquifers exceeded 150 per cent. The continuing decline in the drought's intensity may be traced by reference to Table 1; accumulated rainfall totals from the beginning of October are now within about 15 per cent of the mean in all water authority areas with the exception of Southern Water. The unevenness of the temporal distribution of rainfall is remarkable. For example, the Thames catchment experienced its wettest February-April period in a decade following the driest three-months (commencing in November) in a 106 year record. However, impressively high percentage rainfall totals for March and April can be somewhat misleading - on average these are among the driest months of the year in the South East - and the excess rainfall has been insufficient to fully compensate for the longer term deficiencies in parts of lowland England (see Figure 1). In the 13 -months ending in April 1989, a considerable shortfall may still be recognised in some southern districts and this remains significant in relation to the refilling of reservoirs in one or two catchments.

The low temperatures and limited sunshine during April served to postpone the normal seasonal build-up of soil moisture deficits. Soils remained close to, or at, field capacity until the end of the month when SMDs were between 15 and 30 mm below average throughout central and southern England.

Monthly mean river flows for April were above, or well above, average throughout England and Wales except in rivers which are sustained principally from groundwater. In such catchments flows remain significantly below the mean but are, generally, increasing in response to the recent aquifer recharge and there is every prospect of the late spring flows falling well within the normal flow range (see Figure 2). Table 2 summarises the current runoff situation; of the rivers featured only the Lune, Lud (substantially), Kennet, Test and Itchen registered April runoff
totals below the corresponding figure for 1988; in most catchments runoff was appreciably greater. Accumulated runoff totals since October 1988 are still relatively modest in lowland England but the very healthy discharge rates maintained since early March contrast sharply with the spring flows registered before the sumner droughts of $1959,1964,1973,1976$ and 1984.

Heavy percolation rates.throughout April led to a marked improvement in groundwater resources at a time when water table recessions are normally well established in most areas. Quantifying the improvement is complicated by the different lag times of individual observation wells; these reflect the depth of the wells and the characteristics of the individual aquifer units.

In the Great Oolite aquifer of the Cotswolds groundwater levels peaked in late March/early April - at a level close to the normal spring maximum and are now in decline. By contrast, the water table is still rising in the Chilterns and parts of the North Downs. Generally the delayed recharge has resulted in groundwater levels in early May approaching, or in western districts - exceeding the monthly average. Some further modest response to the April infiltration may be anticipated in the deeper wells but 1988/89 recharge is still minimal in parts of the Yorkshire Chalk (see Fig. 3), northern East Anglia and parts of Kent. In these areas, recharge since last summer is estimated to be less than one quarter of the average, 60-80 per cent of the mean is more typical of the English lowlands with average, or above average, totals in the North West. Although it has been a poor winter in terms of aquifer replenishment, the situation for most of the country is not a matter of concern. Only in the districts mentioned above would a prolonged dry summer result in aquifer conditions even approaching those prevailing in the early autumn of 1976.
