49 Abstract

36 50

38 51 For analysing element input into ecosystems and associated risks due to atmospheric deposition, element concentrations in
39 52 moss provide complementary and time-integrated data at high spatial resolution every five years since 1990. The paper
40 53 reviews (1) minimum sample sizes needed for reliable, statistical estimation of mean values at four different spatial scales
41 54 (European and national level as well as landscape-specific level covering Europe and single countries); (2) trends of heavy
42 55 metal (HM) and nitrogen (N) concentrations in moss in Europe (1990-2010); (3) correlations between concentrations of HM in
43 56 moss and soil specimens collected across Norway (1990-2010); and (4) canopy drip-induced site-specific variation of N
44 57 concentration in moss sampled in seven European countries (1990-2013). While the minimum sample sizes on the European
45 58 and national level were achieved without exception, for some ecological land classes and elements the coverage with
46 59 sampling sites should be improved. The decline in emission and subsequent atmospheric deposition of HM across Europe
47 60 has resulted in decreasing HM concentrations in moss between 1990 and 2010. In contrast, hardly any changes were
48 61 observed for N in moss between 2005, when N was included into the survey for the first time, and 2010. In Norway, both, the
49 62 moss and the soil survey data sets were correlated, indicating a decrease of HM concentrations in moss and soil. At the site

63 level, the average N deposition inside of forests was almost three times higher than the average N deposition outside of
64 forests.

67 Bioaccumulation; bioindication; heavy metals; moss; soil; nitrogen

68

69 **1 Background and objectives**

70

71 Some of the most significant anthropogenic sources of heavy metals (HM) include metals industry (Al, As, Cr, Cu, Fe, Zn),
72 other manufacturing industries and construction (As, Cd, Cr, Hg, Ni, Pb), electricity and heat production (e.g. Hg, Ni), road
73 transportation (Cu and Sb from brake wear, Pb from petrol, Zn from tires), petroleum refining (Ni, V), and phosphate
74 fertilisers in agricultural areas (Cd) (Harmens et al. 2011 a). N emissions and related deposition are due to technical
75 processes and agriculture. Pollutants which were emitted into and transported through the atmosphere finally come down at
76 Earth's surface as wet (rain, snow), occult (fog, mist, rime) or dry (gases, particles) deposition where they accumulate in
77 biota and sediments of terrestrial and subsequently of aquatic ecosystems.

78

79 In Germany, less than 10 % of the HM load of aquatic environments is emitted from industries. More than 80 % of polycyclic
80 aromatic hydrocarbons inputs in aquatic systems are derived from atmospheric deposition. About 72 % of the total N load is
81 due to diffuse sources such as agricultural land use (Böhm et al. 2000, Fuchs et al. 2010). Thus, assessing risks for aquatic
82 sediments necessarily needs spatial valid information on atmospheric deposition onto land surfaces of drainage basins
83 (Böhm et al. 2000; Fuchs et al. 2010) where atmospheric deposition can be collected by technical devices such as
84 permanent open ('bulk') samplers and wet only samplers (Hansen et al. 2013) as well as by biological samplers as for
85 instance moss (Harmens et al. 2015). In contrast to measurements with technical deposition samplers there are only few
86 studies analysing forest tree canopy drip effects on the accumulation of N in moss (Skudnik et al. 2014, 2015) and how this
87 could influence the evaluation of atmospheric deposition patterns in drainage basins with silvicultural land use.

88

89 Over the past and future decades atmospheric deposition has received and will retain considerable attention as an
90 environmental problem since acidifying compounds affects soil, limnic systems, aquatic and terrestrial biota (e.g. fish
91 populations, forest trees), reactive N impacts terrestrial and aquatic ecosystems through nutrient enrichment, and HM

92 accumulate in food chains as well as in soils and sediments (de Witt and Wathne 2015; EEA 2014; Garmo et al. 2014; WGE
1 93 2013). The latter can serve as an important HM source for aquatic ecosystems (EU 2002). Therefore, the Convention on
2 93 3
3 94 Long-Range Transboundary Air Pollution (CLRTAP) was implemented in 1979 to reduce air pollutant emissions in Europe
4 94 5
5 95 and North America and thereby improve the environmental status of terrestrial and aquatic ecosystems. Under the CLTRAP,
6 95 7
7 96 six International Cooperative Programmes (ICP) were launched to assess the impact of atmospheric pollution on ecosystems
8 96 9
9 97 and the effects of emission control, amongst them: *ICP Integrated Monitoring* (2 sites in NE- and SE-Germany, Bringmark et
10 97 11
11 98 al. 2013; Dirnböck et al. 2014), *ICP Assessment and Monitoring of Air Pollution Effects on Forests (ICP Forests)* (66 sites in
12 98 13
13 99 Germany according to Seidling, Email 2015.02.25; Michel and Seidling 2015), *ICP Effects of Air Pollution on Natural*
14 99 15
15 100 *Vegetation and Crops (ICP Vegetation)* (700-1030 moss survey sites in Germany, **section 2.1.1**) and the *ICP Assessment*
16 100 17
17 101 *and Monitoring Effects of Air Pollution on Rivers and Lakes (ICP Waters)* (35 sites in Germany, Garmo et al. 2014). The latter
18 101 19
19 102 aims at monitoring effects of N and HM (Cd, Hg, Pb) atmospheric deposition on water chemistry, on presences / absence of
20 102 21
21 103 aquatic biota and on concentrations in biota and in sediments (Garmo et al 2014; Holen et al. 2013). The objective of the *ICP*
22 103 23
23 104 *Integrated Monitoring* is to investigate the state of ecosystems or catchments regarding the spatial variation and impact of air
24 104 25
25 105 pollutants such as N and HM including effects on biota. Thereby, biomonitoring approaches such as the use of moss as
26 105 27
27 106 natural deposition sampler are included connecting the *ICP Integrated Monitoring* with the *ICP Vegetation* (Meyer et al. 2015
28 106 29
29 107 b).
30 107 31
31 108
32 108 33
33 109 Atmospheric deposition is often used as input parameter for modelling fluxes of N and HM into surface waters (Fuchs et al.
34 109 35
35 110 2010) and can be determined by numeric models such as LOTOS-EUROS (Bultjes et al. 2014; Mues et al. 2014; Schaap et
36 110 37
37 111 al. 2008) and EMEP (Simpson et al. 2014 a, 2014 b) using emission and meteorological data and validated by chemical
38 111 39
39 112 analyses of deposition collected with technical devices such as bulk and wet only samplers (Adriaenssens et al. 2013;
40 112 41
41 113 Hansen et al. 2013) or by biomonitors such as mosses (Harmens et al. 2013 a, 2014, 2015). Due to specific advantages and
42 113 43
43 114 disadvantages afore mentioned approaches should be applied complementarily. Technical sampling enables high time
44 114 45
45 115 resolution, however only a sparse spatial coverage (Tørseth et al. 2012). Benefits using the moss technique are that metals
46 115 47
47 116 accumulate in moss, leading to much higher concentrations than in air, rain and snow and, thus, reducing problems of
48 116 49
49 117 contamination during sampling and analysis (Harmens et al. 2015). Additionally, the moss survey covers large areas of
50 117 51
51 118 Europe and many elements and enables spatially valid estimates of the exposure of drainage basins to atmospheric
52 118 53
53 119 deposition. Therefore, this article concentrates on the moss technique.
54 119 55
55 120
56 120 57
57 121 To map atmospheric deposition and to validate and spatially differentiate measured and modelled deposition values, the use
58 121 59
59 122 of estimates from element concentrations in moss is well established (Harmens et al. 2012; Nickel et al. 2015 a, 2015 b;
60 122 61
61 62
62 63
63 64
64 65

123 Schröder et al. 2012). Since 1990, the moss technique was used for HM surveys encompassing up to 7000 sites across
124 Europe every 5 years (Harmens et al. 2015). By far the most sampling sites are located in forested areas which are of great
125 importance for the quantity and quality of water and sediments in drainage basins. The latest moss survey was conducted in
126 2010. Germany participated in the surveys 1990-2005. Since 2005, N and since 2010 persistent organic pollutants (POP)
127 complemented the chemical analyses of HM in moss (Harmens et al. 2013 a, 2014, 2015). The European moss survey
128 provides complementary and time-integrated data at a high spatial resolution which are used to identify areas at risk of high
129 of atmospheric deposition and assess temporal trends. Thus, the moss data could be used as an additional source to
130 estimate the atmospheric input of pollutants into sediments of catchment basins and aquatic ecosystems and, thus,
131 contribute to the topics *Inputs of pollutants and risk assessment in context with the Water Framework Directive* of the
132 International Conference Contaminated Sediments 2015. In this context, the paper at hand introduces the European moss
133 survey as a suitable data base for quantifying the contamination of terrestrial and aquatic sediments due to atmospheric
134 deposition – directly through atmospheric deposition onto water surfaces and indirectly through run off from terrestrial
135 surfaces of drainage areas exposed to deposition (Downs et al. 1998; Schwesig and Matzner 2001). To this end,
136 investigations at different spatial scales relevant for risk assessments of catchments were conducted dealing with the
137 following questions:

- 138 1. Are there enough sample sites for reliable statistics for Europe as a whole, single countries and ecologically defined land
139 classes covering Europe (methods **Sections 2.2.1**, results: **Section 3.2**)?
- 140 2. What are the trends of HM and N atmospheric deposition from 1990-2010 (HM) and 2005-2010 (N), respectively (methods
141 **Sections 2.1.1** and **2.2.2**, results: **Section 3.3**)?
- 142 3. Are HM concentrations in moss correlated with HM concentrations in soil and, thus, due to leaching of HM from soil,
143 indicate a potential risk for aquatic ecosystems and their sediments (investigation at *national level by example of Norway*,
144 methods **Sections 2.1.2** and **2.2.3**, results **Section 3.4**)?
- 145 4. Do N concentrations in moss samples reflect *site*-specific variance due to the filter effect of vegetation canopies (methods
146 **Sections 2.1.3** and **2.2.4**, results **Section 3.5**)?

148 2 Materials and Methods

150 2.1 Sampling and chemical analyses

152 2.1.1 Trends of HM (1990-2010) and N (2005-2010) concentrations in moss collected across Europe

154 The trend analysis detailed in sections 2.2.2 and 3.3 was based on moss specimens collected between 1990 and 2010
1 across Europe. Based on experience with Norwegian moss surveys in 1977 and 1985 relying on around 460 sampling sites
2 155 across Europe. Based on experience with Norwegian moss surveys in 1977 and 1985 relying on around 460 sampling sites
3
4 156 (Steinnes et al. 2011), since 1990 the European moss survey has been providing data on HM and since 2005 on N
5
6 157 concentrations in naturally growing moss following a harmonized methodology for sampling, chemical analyses and quality
7
8 158 control ensuring spatial and temporal comparability. The latest manual was updated for the 2015 survey (ICP Vegetation
9
10 159 2014). The concentration of HM (expressed as mg kg⁻¹ dry weight at 40° C) and N (in [%] or [mg g⁻¹] of dry weight at 40° C)
11
12 160 were determined by several analytical techniques such as Inductively Coupled Plasma Optical Emission Spectrometry
13
14 161 (sometimes referred to as an ICP-Atomic Emission Spectrometry), ICP Mass Spectrometry or Neutron Activation Analysis
15
16 162 (Barandovski 2015; Harmens et al. 2013 c; Špirić et al. 2012, 2013, 2014 a, 2014 b). Quality control exercises are based on
17
18 163 moss reference material M2, containing elevated concentrations for most metals, and M3, containing background
19
20 164 concentrations for most metals (Steinnes et al. 1997). Recommended values for the N concentration in M2 and M3 were
21
22 165 established in the 2005 European moss survey. In addition, some laboratories used other certified reference material for
23
24 166 quality assurance (Harmens et al. 2010, 2011 b, 2013c, 2014, 2015; Kluge et al. 2013; Meyer et al. 2015 a, 2015 b; Schröder
25
26 167 et al. 2009).

27
28 168
29
30 169 The European moss survey provides data on concentrations of at least ten HM (As, Cd, Cr, Cu, Fe, Hg, Ni, Pb, V, Zn) in
31
32 170 naturally growing mosses, and since 2005 also for Al, Sb and for N. By far more metal elements are determined in some
33
34 171 countries such as Albania and Macedonia (Barandovski et al. 2015; Qarri et al. 2013). In 2010, a pilot study was conducted
35
36 172 on the application of mosses as biomonitors of selected POPs (Harmens et al. 2013a, 2013 b). The HM data reported from
37
38 173 the European surveys 1990 and 1995 were based on moss specimens collected at 4661 (Germany 592, Norway 458) and
39
40 174 7311 (Norway 458) sites, respectively. In the 2000 / 2001 survey moss specimens were sampled at almost 7000 (Norway
41
42 175 464) sites in 29 European countries (Harmens et al. 2004). In 2005 / 2006 the HM concentrations were derived from moss
43
44 176 specimen sampled at more than 7000 sites (Norway 464) in 32 European countries and the N concentrations from moss
45
46 177 collected at 3200 sites (Norway without N measurements) (Harmens et al. 2006). 25 European countries reported on HM
47
48 178 concentrations in moss sampled at over 4500 sites and on N concentrations in moss specimens sampled at roughly 2400
49
50 179 sites in 15 countries 2010 / 2011 (Norway 464). Germany did not participate in this survey "leaving a big gap in the data for
51
52 180 central Europe" (Harmens et al. 2015).

53
54 181
55
56 182 In 2010, *Pleurozium schreberi* was the moss species most frequently sampled across Europe (ca. 42 %), followed by
57
58 183 *Hylocomium splendens* (23.5 % and 15.3 % for HM and N, respectively), *Hypnum cupressiforme* (19.6 % and 26.9 %,
59
60 184 respectively), *Pseudoscleropodium purum* (7.7 % and 7.5 %, respectively) and other species (7.1 % and 8.7 %, respectively).

185 For quality assurance purposes moss reference material (Steinnes et al. 1997) was used. Where necessary, correction
186 factors were applied to outliers, and in some cases severe outliers were excluded from further data processing (Harmens et
187 al. 2015; Meyer et al. 2015 b). In all survey years, the reported data were checked for anomalies and the format harmonized
188 before maps were produced. The maps display the spatial pattern of HM and N concentrations across Europe on a 50 km by
189 50 km grid enabling a direct comparison with the atmospheric total HM and N deposition modelled by EMEP. Additional
190 computations allowed for mapping element concentrations in moss with a significant higher spatial resolution (Schröder et al.
191 2012, 2013, 2014).

192

193 2.1.2 Correlation of HM concentrations in moss and soil sampled across Norway 1990-2010

194

195 The data base for correlation analyses (sections 2.2.3, 3.4) were moss and soil samples collected across Norway mainland.
196 The moss data were derived from specimens collected in 1990, 1995, 2000, 2005 and 2010 at 458 to 464 sites distributed
197 across the mainland of Norway according to the harmonized European protocol (section 2.1.1; Steinnes et al. 2011, 2013).
198 At nearly the same sites, samples of natural organic surface soils were collected in 1995 and 2005 according to a procedure
199 described by Nygård et al. (2012).

200

201 2.1.3 Variation of N concentrations in moss at site level due to canopy drip effects

202

203 Up to now, only few studies on canopy effects on N concentration in moss were published (Skudnik et al. 2014, 2015). This
204 investigation of canopy drip effects on N concentrations in moss (sections 2.2.4, 3.5) relies on two data bases, one
205 published by Kluge et al. (2013) and Meyer et al. (2015 a) and the other by Harmens et al. (2014), which were compiled and
206 assessed statistically by Meyer et al. (2015 b).

207

208 Since spatial dense deposition monitoring with technical samplers such as bulk and wet-only samplers is rare (Tørseth et al.
209 2012) but feasible with the moss technique, we systematically examined whether the filter effect of forest stands for
210 atmospheric N deposition as already confirmed by technical deposition samplers for single sites could be corroborated by
211 use of moss and, thus, applied for surveys covering areas of large spatial extend. To this end, in addition to the
212 measurement of N concentration in mosses sampled at 720 sites across Germany in 2005 (Section 2.1.1) a systematic
213 investigation of canopy drip-related variation of N concentration in moss was conducted (Kluge et al. 2013; Meyer et al. 2015
214 a, 2015 b). The moss specimens were sampled in 2012 and 2013 across North-western Germany beneath tree canopies (in

215 the following referred to as “throughfall sites”, n = 30) and at adjacent (i.e. 2 km distance at maximum) places outside of
216 peripheral tree canopies (“open sites”, n = 26) which in the following are referred to as ‘DE-NI_12 / 13’. These
217 measurements were joined with respective data derived from a study dealing with the statistical relation between site-specific
218 N concentrations in mosses and measured atmospheric N deposition across Europe sampled in Austria (AT), Switzerland
219 (CH), Germany (DE), Spain (ES), Finland (FI), France (FR), and Slovenia (SI) between 1998 and 2012 (Harmens et al.
220 2014). *Pleurozium schreberi* was collected most frequently (n = 136; 48 %) followed by *Pseudoscleropodium purum* (n = 69;
221 24 %), *Hypnum cupressiforme* (n = 58; 20%), *Hylocomium splendens* (n = 10; 4 %), *Thuidium tamariscinum* (n = 9; 3 %) and
222 *Abietinella abietina* (n = 2; 1 %). In accordance with the investigation purposes, moss samples were collected either outside
223 of the peripheral tree canopy (“open sites”) as holds true for AT, CH, DE, FI, and SI (n = 147) or inside (in the following
224 referred to as “throughfall sites”) in DE, ES, and FR (n = 137).

225
226 Sampling, preparation and chemical analyses were conducted according to the guidelines of the European moss survey
227 (Section 2.1.1) and described by Harmens et al. (2013 c, 2014) and Meyer et al. (2015 a, 2015 b). Accordingly, for quality
228 control purposes, moss reference materials M2 and M3 (Steinnes et al. 1997) were used in all participating countries except
229 for DE (1998-2010) using reference materials according to DIN standards (DIN EN ISO 17025). For ‘DE-Ni_12 / 13’, certified
230 reference material reviewed by inter-laboratory tests was used for quality assurance (Meyer et al. 2015 a, 2015 b).

231

232 2.2 Statistics

233

234 2.2.1 Calculation of minimum number of sampling sites needed for reliable statistics

235

236 Measurement values should be meaningful not only for single observed points in space and time but should rather allow for
237 spatial and temporal generalizations so that the number of samples required should be based on a specified confidence
238 interval of the mean of the variable considered (Nelson and Ward 1981). Therefore, the minimum number of sampling sites
239 (MSS) needed for reliable statistics were calculated for concentrations of Al, As, Cd, Cr, Cu, Fe, Hg, N, Ni, Pb, S, Sb, V, and
240 Zn in moss collected in 2010. The minimum number was computed for (a) Europe in terms of the sum of the territories of
241 countries which participated in both moss surveys; (b) each of the participating countries; (c) each of the 40 Ecological Land
242 Classes of Europe (ELCE 40) covering the whole Europe and (d) for each ELCE unit within the participating countries
243 covered by the survey network. This spatial differentiation is of importance since the landscape specific differentiation (c) is
244 not fixed to administrative boundaries. However, while some of the participating countries might comply with the MSS for a

245 certain element the MSS potentially could not be reached when considering the MSS of specific landscapes within the
1
2 246 respective country (d).

3
4 247
5
6 248 For calculating the minimum sample number needed to adequately cover the ecoregions of Europe the data on HM and N
7
8 249 concentrations in moss collected 2010 (HM, N) were linked to a map of ecological land classes across Europe. This map was
9
10 250 calculated by means of Classification and Regression Trees (CART; Breimann et al. 1984) from 48 digital maps each
11
12 251 depicting the spatial pattern of one of 48 ecologically relevant characteristics of landscapes / drainage basins covering
13
14 252 climate, altitude, soil, and potential natural vegetation in Europe. ELCE subdivides Europe into spatial units mapped on grids
15
16 253 of about 20 km by 20 km (Schröder et al. 2014) (Figure S1 and Table S1).

17
18 254
19
20 255 As the majority of moss data were not normally distributed, a different treatment of these data was necessary to calculate the
21
22 256 MSS values: For those moss data, that were not normally distributed concerning the respective spatial scale, logarithmic
23
24 257 transformation – in fact, natural logarithm of base e – to approximate normal distribution and MSS-formula (2) were applied
25
26 258 instead of the MSS-formula (1). For normally distributed moss data, MSS values were calculated by means of the original
27
28 259 MSS-formula (1).

29
30 260
31
32 261 (1) MSS-formula of the moss-manual (ICP 2014)

$$MSS = \left(\frac{1.96 * Stdev}{tol * Mean} \right)^2$$

33
34
35
36
37
38 262
39
40 263 (2) MSS-formula according to Wosniok (2015)

$$MSS = -\frac{B}{4A} + \sqrt{\left(\frac{B}{4A}\right)^2 - \frac{Stdev_{log}^2}{A}}$$

41
42
43
44
45
46
47 264 with:

$$A = \left(\frac{1}{1.96} \left\{ \ln[Mean * (1 + tol)] - Mean_{log} - \frac{Stdev_{log}^2}{2} \right\} \right)^2$$

$$B = -2A - 2 * Stdev_{log}^2 - Stdev_{log}^4$$

$$Mean_{log} = \ln(Mean) - \frac{Stdev_{log}^2}{2}$$

$$Stdev_{log} = \sqrt{\ln\left(1 + \frac{Stdev^2}{Mean^2}\right)}$$

265 Stdev = Standard deviation of measured element concentration in mosses

266 1.96 = Z-value, indicating significance level of 0.05

267 tol = Error tolerance, here: 0.2 (= 20 %)

268 Mean = Mean value of measured element concentration in mosses

269

270 The idea of determining the minimum number of sampling sites is, to ensure a maximal distance of 'tol * Mean' between
 271 empirical and true mean at a significance level of 0.05. MSS-formula (2) is based on the 'Cox method' (mentioned as
 272 'personal communication' in Land 1971 as cited in Olsson 2005) for calculating confidence intervals for the mean of a log-
 273 normal distribution. For calculating MMS, the Cox equation was resolved by Wosniok (2015).

274

275 2.2.2 Trends of HM (1990-2010) and N (2005-2010) concentrations in moss collected across Europe

276

277 Statistical analyses of temporal trends derived from data collected in 1990, 1995, 2005 and 2010 across Europe were
 278 performed as described by Harmens et al. (2010). Accordingly, for each metal, data were only included for those countries
 279 that had determined the element concentrations for at least four out of the five survey years. However, for Hg some countries
 280 were also included that had reported data for three out of the last four survey years. Regarding Al, Sb and N, the
 281 development was determined between 2005 and 2010. For HM, a general linear model with the geometric mean as the
 282 response and country and year as factors was then run. Tukey tests applied for pairwise element-specific comparisons
 283 between years (Harmens et al. 2015).

284

285 2.2.3 Correlation of HM concentrations in moss and soil collected across Norway 1990-2010

286

287 *Descriptive and correlation statistics, and testing for significant differences between surveys*

288

289 Basic descriptive statistical measures (number of sites, minimum, maximum, median) for the concentrations of As, Cd, Cr,
 290 Cu, Fe, Hg, Ni, Pb, Ti, Sb, V, and Zn in moss were calculated for specimens collected in 1990, 1995, 2000, 2005, and 2010
 291 as well as for natural surface soil sampled in 1995 and 2005. Wilcoxon signed rank test were applied to investigate whether
 292 significant differences between the data from different monitoring campaigns exist.

293

1
2 294 Correlations between the Cd, Hg and Pb concentrations in moss and soil were computed according to Spearman (1904) (r_s).

3
4 295 Since soil data were available only for the years 1995 and 2005, HM concentrations in mosses collected from 1990, 1995

5
6 296 and 2000 were compared to the HM concentrations in soil specimen from 1995, whereas the HM concentrations in moss

7
8 297 sampled in 2000, 2005 and 2010 were compared to the HM concentrations in soil samples from 2005. The correlations

9
10 298 between the measured HM concentrations in moss samples collected in 1990 with the measured HM concentrations in soil

11
12 299 specimen sampled in 1995 included only those soil sampling sites which were situated no more than 2 km away from the

13
14 300 moss collection sites. The sampling sites for moss and soil were identical in 1995 as well as in 2005. The correlation

15
16 301 analyses based on measured HM concentrations in moss and soil samples were complemented by correlation analyses

17
18 302 including geostatistically estimated HM concentrations which were computed to estimate potential bias due to surface

19
20 303 estimation and by analyses of correlations between measured HM concentrations and potential predictors for element

21
22 304 concentrations in moss and soil.

23
24 305

25
26 306 *Identification and ranking potential predictors for element concentrations in moss and soil*

27
28 307

29
30 308 In order to uncover and rank multivariate relationships of the HM concentrations in moss and natural surface soil with

31
32 309 potential influencing environmental factors as predictors of HM concentration in moss and soil samples, classification and

33
34 310 regression trees (CART) were computed. Thereby, four approaches (A) should enable investigating whether moss and soil

35
36 311 indicate similar environmental conditions: Measured concentrations of Cd, Hg, and Pb in moss samples were set as target

37
38 312 variable and related to predictors including (A1) / not including (A2) geostatistically estimated HM concentrations in natural

39
40 313 surface soil. Additionally, measured concentrations of Cd, Hg, and Pb in natural surface soil were set as target variable

41
42 314 including (A3) / not including (A4) geostatistically estimated HM concentrations in moss samples as environmental predictor.

43
44 315 The geostatistical estimation of concentration values have each been carried out because the geographical coordinates of

45
46 316 moss and soil sampling sites did not match exactly in all cases. Contrary to approaches 1, 3 and 4, approach 2 was

47
48 317 calculated not only for Cd, Hg, and Pb but also for As, Cr, Cu, Fe, Ni, Sb, Ti, V, and Zn. The following characteristics of

49
50 318 terrestrial landscapes and drainage basins, respectively, were regarded as predictors: distance to the North Sea [km] as

51
52 319 parameter for potential sea spray effect; elevation above sea level [m] (GLOBE, 1 km by 1 km, Hastings et al. 1999);

53
54 320 precipitation 1991-2002 [mm / a] (20 km by 20 km, New et al. 2002); percentage of agricultural, forestall and urban land use

55
56 321 [%], respectively, each in 1 km and 5 km radius around sampling sites derived from Corine Land Cover maps 2000 and 2006

57
58 322 (Büttner et al. 2012); population density [residents / km²] (grid data in a 5 km by 5 km resolution on population densities for

59
60 323 the years 1990, 1995, 2000 and estimated for 2005, 2010 and 2015, GPW version 3, CIESIN / FAO / CIAT 2005); soil

324 texture in terms of percentages of clay, silt and sand in the upper soil [%] (1 km by 1 km, FAO / IIASA / ISRIC / ISSCAS /
1 JRC 2009); modelled total atmospheric deposition (EMEP; 50 km by 50 km grid; Gusev et al. 2010): Cd - 3 years' sum [μg
2 325 $\text{m}^{-2} \text{a}^{-1}$], Hg - 3 years' sum [$\mu\text{g} \text{m}^{-2} \text{a}^{-1}$], and Pb - 3 years' sum [$\mu\text{g} \text{m}^{-2} \text{a}^{-1}$]; geostatistically estimated concentrations of Cd, Hg
3 326 and Pb in moss and soil [$\mu\text{g} \text{g}^{-1}$].
4 327
5 328

6 329 For the HM concentrations in moss, the median for each of the EMEP 50 km by 50 km raster cells (Gusev et al. 2010) was
7 330 used for the correlation analysis. With exception of 1990, the 3-year sum of the modelled deposition values, preceding the
8 331 time of the sampling of the moss specimen, were calculated and assigned to each EMEP cell since the analysed moss
9 332 shoots represent the recent 3 years of growth. For 1990 moss values, only modelled atmospheric total deposition data from
10 333 that same year was available.
11 334

12 335 *Geostatistical evaluation of spatial validity*

13 336
14 337 To investigate the validity of the monitoring network and, respectively, the spatial patterns and temporal trends of the
15 338 measured Cd, Hg and Pb concentrations in moss (1990, 1995, 2000, 2005 and 2010) and in soil (1995, 2005), geostatistics
16 339 were applied. To this end, variogram analysis and Kriging procedures were carried through by use of the ESRI ArcGIS 10.1
17 340 extension Geostatistical Analyst (ESRI 2011). Since all element concentrations showed highly right-skewed data distributions
18 341 and clear spatial drifts, Lognormal Universal Kriging was applied to calculate surface maps for Cd, Hg and Pb concentration
19 342 in Norwegian moss and soil samples in a spatial resolution of 5 km by 5 km. The quality of estimation was calculated by use
20 343 of cross-validation and by correlation of measured and geostatistically estimated HM concentrations.
21 344

22 345 *Correlation of measured and geostatistically estimated HM concentrations*

23 346
24 347 The surface maps calculated by use of the Kriging estimation were used to analyse the correlation between both the
25 348 measured Cd, Hg and Pb concentrations in moss and the spatially estimated HM concentrations in soil, and the measured
26 349 Cd, Hg and Pb concentrations in soil and the spatially estimated HM concentrations in moss for the surveys 1995 and 2005.
27 350

28 351 **2.2.4 Variation of N concentrations at site level due to canopy drip effects**

29 352

353 In analogy to the investigations in Norway, for characterisation of the sampling sites and to identify the most relevant
1
2 354 environmental factors associated with the N concentrations in moss, the following geodata were spatially connected with the
3
4 355 sampling locations: percentages for agricultural, forested and urban areas within a radius of 1 and 5 km around the moss
5
6 356 sampling sites were calculated based on the Corine Landcover map 2006 (Büttner et al. 2012), population density (CIESIN,
7
8 357 FAO, CIAT 2005), altitude above sea level (a.s.l.) (Hastings et al. 1999), precipitation (New et al. 2002), distance of the
9
10 358 sampling sites to the North Sea, gridded data on modelled atmospheric total N deposition including wet and dry deposition of
11
12 359 oxidized and reduced N in a resolution of 50 km by 50 km (provided by EMEP MSC-W; Simpson et al. 2014 a, b). Taking into
13
14 360 account the two to three years growth of moss, the modelled atmospheric total N deposition was averaged over the previous
15
16 361 three years integrating the respective year of sampling and the previous two years and then intersected with the particular N
17
18 362 content in moss (Meyer et al. 2015 b).

19
20
21 363

22 364 3 Results and discussion

23
24
25 365

26
27 366 The results of the moss surveys are spatially valid not for single measurement points but for large areas such as drainage
28
29 367 basins, ecoregions, national territories and Europe as a whole. Up to now, the calculation of element loads of aquatic
30
31 368 ecosystems was based on deposition values with little empirical validation (Fuchs et al. 2010). The moss monitoring data are
32
33 369 recommended to improve that situation.

34
35 370

36 37 371 3.1 Quality control

38
39 372

40
41 373 According to Dołęgowska and Migaszewski (2015) and Schröder et al. (1991, 2009) environmental studies need a
42
43 374 transparent documentation of selecting sampling sites, collection of specimens, chemical and physical measurements and
44
45 375 statistical data analysis. Regarding the European moss survey, these requirements are realised pretty good. Generally, data
46
47 376 obtained indicated acceptable agreement between laboratories. In 2010, the mean values ranged from 85 % for As to 105 %
48
49 377 (Sb) of the recommended values for M2 and from 92 % (Cr) to 113 % (As) for M3. For N, the mean values of M2 and M3
50
51 378 were 101 % and 102 % of the recommended value respectively. Correction factors were applied when both M2 and M3
52
53 379 values were outliers for a specific metal, and sometimes corrections factors were also applied when only one reference value
54
55 380 was identified as an outlier (Harmens et al. 2015). Although applying correction factors enhanced compatibility of data
56
57 381 between countries, it hardly affected the overall European mean and median values for the elements. As a consequence, it
58
59 382 did not significantly affect the temporal trends reported for the whole of Europe. The results of quality control exercises were
60

383 reported by Harmens et al. (2010, 2011 b, 2013c, 2014, 2015), Kluge et al. (2013), Meyer et al. (2015 b), and Schröder et al.
1 384 (2009).
2
3

4 385

6 386 3.2 Calculation of minimum number of sampling sites needed for reliable statistics

7 387

10 388 The minimum sample size for the European moss surveys 2005 and 2010 was computed ex-post but not a priori and, thus,

12 389 applied to the already existing networks. Regarding those 40 ELCE units which were covered by the European moss survey

14 390 2005, in most cases the number of sampled sites (realized sample size - RSS) reached the number of sites required (MSS)

16 391 to calculate valid statistically reliable N concentrations in moss. The minimum number of sampling sites required had failed in

18 392 three out of 27 ELCE units (11.1 %) with N determined in mosses: in these three land classes, 27 sites instead of 12, 6

20 393 instead of 2, and 8 instead of 4, should have been sampled, respectively. The determination of minimum numbers of

22 394 sampling sites needed for calculating reliable mean values for Europe as a whole and for each of the 16 countries

24 395 participating in the moss survey 2005 revealed a similar picture as found for ELCE landscapes as spatial reference system.

26 396 The number of sampling sites was shown to be adequate to estimate reliable statistics on the N concentrations in moss

28 397 sampled in 2005 (Schröder et al. 2014). To capture the spatial variability of atmospheric N deposition and N concentrations

30 398 in mosses, it should be emphasized that the guidance on sampling density as provided in the moss monitoring manual (ICP

32 399 Vegetation 2015) should be followed. As indicated above for the ELCE units, the spatial scale of the statistical analysis

34 400 determines whether the current network density is sufficient or not to obtain reliable statistics.

36 401

38 402 In the European moss survey 2010 moss were sampled at 4.499 sites in 25 countries and 14 elements were determined. For

40 403 each of the elements the minimum sample size was calculated and compared to the realised sample number for Europe as a

42 404 whole, each participating country and landscape-specific across Europe (Table 1) and each participating country (Table 2) ,

44 405 to provide an indication of statistical reliability at different spatial scales. Regarding Europe as a whole, the realized sample

46 406 size (RSS) reaches the required minimum sample size (MSS) in all cases of the 14 considered elements. However, this

48 407 holds not true when considering lower spatial levels. On a national scale, only two (N, S) of the 14 considered elements

50 408 comply with the required sample size in 100 % of the countries in which the respective elements were collected. For all other

52 409 elements the MSS is reached by 58 % to 90 % of the participating countries. On the other hand, 6 out of the 25 participating

54 410 countries, so nearly 24 %, reach the MSS for all elements that were collected by the respective country. When considering

56 411 the ELCE units (Figure S1 and Table S1), which in contrast to the administrative areas of the national states constitute not

58 412 do be contiguous areas, some differences compared to the national level were found. Moss sites are located in 32 of the 40

60 413 ELCE units (Table 1). However, none of the 14 examined elements reach the MSS in all ELCE units where moss specimens

414 were sampled. The lowest percentage was calculated for AI reaching the MSS in only 34 % of the ELCE units containing
1
2 415 sample sites with AI measurements. But by taking a differentiated look at the particular ELCE units at least four of the 32
3
4 416 ecoregions containing sampling sites comply with the MSS for all elements measured within the respective ecoregion. On the
5
6 417 other hand, in comparison to the national level, ecoregions with very low percentage of sufficient MSS per element were
7
8 418 found: Unit F4_1 (11 %) and Unit L_2 (8 %) and Unit D_10 (7 %). In unit M_6, none of the measured elements reaches the
9
10 419 MSS. Concerning the level of compliance of the particular ELCE units as shown in **Table 2** for Cd, Hg, Pb and N, three-digit
11
12 420 absolute values for MSS were reached within many ecoregions, which corresponds with the results on the national scale.
13
14 421 Highest compliance was calculated for unit F4_2 in case of N.

15
16 422
17
18 423 **Table 1.** Element-specific minimum and realised sample size for different landscapes across Europe by example of Cd, Hg,
19
20 424 Pb and N, survey 2010

21
22 425
23
24 426 Considering the lowest spatial scale – the ELCE units within each participating country – it turned out that none of the
25
26 427 elements reaches the MSS in 100 % of the ELCE units of the single participating countries. As ELCE units are not
27
28 428 continuous across Europe, one specific unit may occur in more than one country. Thus, the "total n" may contain one specific
29
30 429 ELCE unit several times. Therefore, "total n" exceeds the number of different ELCE units within Europe as a whole (n = 40).
31
32 430 Based on "total n", deviations were calculated to examine for each element, the absolute number (MSS complied (n) and
33
34 431 MSS not complied (n)) and the relative number (MSS complied (%) and MSS not complied (%)) of ELCE units within the
35
36 432 single participating countries that fulfill the required MSS or do not, respectively. As **Table 2** shows, a maximum was
37
38 433 calculated for N and S for which at least 76 % and 80 % of the landscapes within the single countries reach the MSS. But
39
40 434 more than half of the 14 analysed elements do not reach even 50 %. Regarding the ELCE units within the single countries
41
42 435 particularly, in 8 % of the cases MSS was reached for all elements sampled within the respective unit of a certain country. In
43
44 436 13 % of the cases the MSS was not reached for all sampled elements. Furthermore, the analysis revealed that indeed some
45
46 437 landscapes comply with the MSS regarding the European level. However, when examining the same landscape within a
47
48 438 single participating country, this fact is not holding true anymore in some cases.

49
50 439
51
52 440 **Table 2.** Element-specific minimum and realised sample size for different landscapes within each participating country for 14
53
54 441 elements, survey 2010

55
56 442
57
58 443 The computations indicate that the compliance achieved for Europe as a whole and single countries, respectively, is now
59
60 444 lower when statistics are conducted at the landscape level. This suggests that MSS is dependent on the scale of interest of a

445 study, hence, following the MSS guidance from a higher spatial level would be not valid if one would like to determine
1
2 446 concentrations in mosses reliably at the landscape or even a smaller scale as for instance protected habitats or sites. In
3
4 447 summary, from the results shown, it is clear that the requirement for MSS is very much dependent on the aim and scale of a
5
6 448 study and the questions it is trying to answer.

7
8 449

10 450 3.3 Trends of HM (1990-2010) and N (2005-2010) concentrations in moss sampled across Europe

11
12 451

13
14 452 In general, mosses from countries in Northern Europe had the lowest HM concentrations, whereas countries in Eastern and
15
16 453 South-eastern Europe had the highest. Averaged across Europe, since 1990, the median concentration in moss specimens
17
18 454 has declined the most for Pb (77 %), followed by V (57 %), Cd (51 %), Cr (43 %), Zn (34 %), Ni (33 %), Fe (27 %), As (21 %,
19
20 455 since 1995), Hg (14 %, since 1995) and Cu (11 %) (Harmens et al. 2013, c, 2015) (Table 3). The average modelled Cd and
21
22 456 Pb deposition in the EMEP domain has declined by 51 % and 74 %, respectively. Between 1995 and 2010, the average Hg
23
24 457 concentration in mosses has decreased by 23 %, whereas the average modelled Hg deposition (EMEP) has declined by 27
25
26 458 %. For other metals, the decline in concentrations in mosses also follows the decline in reported emissions since 1990, with
27
28 459 the lowest decline being reported for Cu concentrations in mosses and absolute emissions.

29
30 460

31
32 461 Table 3. Decline in the average median HM and N concentrations in moss specimens since the start of the European moss
33
34 462 survey in 1990a and since the survey in 2005b (Harmens et al. 2013 c, 2015)

35
36 463

37
38 464 As in previous surveys, the lowest concentrations of HM in moss sampled 2010 were generally found in Northern Europe.
39
40 465 Low to intermediate HM concentrations in moss were generally observed in western and Central Europe. The highest
41
42 466 concentrations were often found in (South-)Eastern Europe. The spatial patterns of Hg and Zn concentrations in moss were
43
44 467 more homogeneous across Europe. On a national or (eco)regional scale deviations from the general European trend occur
45
46 468 (Schröder et al. 2013, 2014). Therefore, even in times of generally decreasing metal deposition across Europe, temporal
47
48 469 trends can differ between geographical scales.

49
50 470

51
52 471 From 2005 to 2010, the average N concentration in moss declined by 5 %. The spatial pattern of the N concentration in
53
54 472 mosses in 2010 / 11 was similar to that in 2005 / 2006, with lower values being observed for Finland than the rest of Europe.
55
56 473 High concentrations of N were found in western and central Europe. The small decrease in the average median N
57
58 474 concentration in mosses is in agreement with the 7 % decline reported by EMEP for modelled total N deposition in the EU27
59
60 475 since 2005. Analyses of the relationship between nitrogen concentration in mosses and EMEP-modelled total nitrogen

476 deposition showed considerable scatter with saturation occurring at a total nitrogen deposition rate of ca. 15 kg N ha⁻¹ a⁻¹.
1
2 477 However, in some countries a linear relationship has been observed between the total N concentration in mosses and
3
4 478 measured bulk N deposition at the site level (Harmens et al. 2015, 2011 b).
5
6 479
7
8 480 N concentrations in herbarium moss specimens collected between around 1860 and 2000 in the Czech Republic, Finland,
9
10 481 France and Switzerland did not change before 1960. After 1960, the total N concentration in mosses has increased in these
11
12 482 countries. Total N deposition rates modelled by EMEP / MSC-West show a similar trend with not much change in total N
13
14 483 deposition rates up to 1960 (apart from the Czech Republic) and a clear rise since 1960 (Harmens et al. 2006). Highest
15
16 484 exceedances of critical loads for acidification of freshwaters and forests by atmospheric deposition occurred in 1980. At that
17
18 485 time, the critical loads for acidification of ecosystems were exceeded on 43 % of the EU-28 area. By 2020, the area where
19
20 486 critical loads are expected to be exceeded and the absolute magnitude of exceedances is expected to be as low as they
21
22 487 were in 1880, i.e. 4 % of the EU-28 area (EEA 2014). Nevertheless, the recovery from acidification will take decades even if
23
24 488 they receive deposition lower than the critical loads (Skjelkvåle and de Wit 2011). The largest coverage with exceedances of
25
26 489 critical loads for eutrophication was reached in 1990 with 79 % of the EU-28 area. This percentage is expected to decrease
27
28 490 to 54 % in 2020, and the absolute magnitude of exceedances will also be reduced in most areas. North-western Germany
29
30 491 will be one of the remaining hot spot areas for N. Even if all technically feasible reduction measures are implemented, the
31
32 492 area at risk of eutrophication would still be 51 % in the EU-28 in 2030 (EEA 2014). Simpson et al. (2014 b) projected the area
33
34 493 of ecosystems exceeding critical loads to 50% and in case of a possible climate-induced increase to 57 % for NH₃ emission
35
36 494 rising by 30 %. However, it should be noted that for 2005, the atmospheric deposition measured and spatially modelled by
37
38 495 the Norwegian Institute for Water Research was 69 % higher for sulphur and 98 % higher for N than the EMEP deposition.
39
40 496 Considering the modelled EMEP deposition, the exceedances of critical loads amount for 8 % (2005) and 2% (2020),
41
42 497 respectively. The corresponding values using deposition data from the Norwegian Institute for Air Research are 18.5 % and
43
44 498 9.5 %. Thus, in European overviews based on EMEP deposition (EEA 2014), the situation in Norway and other countries
45
46 499 may appear better than it really is (Austnes 2015). Assuming the implementation of abatement techniques under Current
47
48 500 *LE*gislation in 2010 (*CLE*2010) and in 2020 under *Full Implementation* of the Aarhus protocol (*FI*2020), a comparison of the
49
50 501 critical loads and atmospheric depositions of Cd, Hg and Pb in these years revealed that Cd deposition is not a widespread
51
52 502 risk in any years. However, Pb deposition was calculated to be exceeded about 22 % and 16 % of natural European area in
53
54 503 2010 and 2020, respectively, and Hg deposition to affect an area of more than 74 % in both years (Hettelingh et al. 2015).
55
56 504
57
58 505 Filtering atmospheric deposition and recycling water, forests are of great importance for the quantity and quality of water in
59
60 506 drainage basins and their terrestrial and aquatic sediments (Likens and Bormann 1995). Long-term monitoring clearly
61
62
63
64
65

507 documents that surface waters respond to changes in atmospheric deposition: From 1990 to 2008 the concentrations of
1 sulphate and nitrate (NO₃) in precipitation and surface waters have decreased in large areas in Europe and North America
2
3
4 509 due to emission reductions which were more distinct between 1990 and 1999 than from 1999 to 2008. NO₃ did not show
5
6 510 uniformly decreasing trends despite the decrease in N deposition. The acidity of lakes and rivers decreased due to the
7
8 511 decrease in sulphate. Although recovery of aquatic biological communities could be monitored a return to pre-industrial
9
10 512 biodiversity is unlikely in most cases because original species were extinct. That is why in several regions of Europe a good
11
12 513 water quality will not be achieved with current legislation of emissions of acidifying components (Futter et al. 2014; Skjelkvåle
13
14 514 and de Wit 2011).

15
16 515
17
18 516 Even if the atmospheric deposition of HM declined throughout the last 25 years across Europe, it still remains high in the
19
20 517 south-eastern European countries (Harmens et al. 2010). The HM pools in soils were and will be progressively filled up and
21
22 518 constitute a latent risk to aquatic ecosystems (Bringmark et al. 2013). This gets obvious when assessing the toxicological
23
24 519 potential of Hg (EU 2002). In fish, levels of Hg usually exceed the European environmental quality standard as set by the
25
26 520 WFD to 20 µg Hg kg⁻¹ fresh weight, whereby recent pollution was mainly ascribed to the diffuse atmospheric input. In
27
28 521 Bavaria, for example, 98 % of the fish muscle samples exceeded the environmental quality standards for Hg between 2007
29
30 522 and 2009 (Lepom et al. 2013; Schäfer et al. 2015). Hg concentrations in fish collected during 2005-2010 from European
31
32 523 lakes (Como, Geneva, Iseo, Lugano, Maggiore) and rivers (Rhine, Rhone) exceeded the above mentioned quality standard
33
34 524 by 2- to 16-fold (Vignati et al. 2013). Akerblom et al. (2014) investigated Hg levels in Swedish freshwater fish during almost
35
36 525 50 years based roughly 44927 observations from 2881 waters. The EU environmental quality standard was exceeded in all
37
38 526 waters. Trend analyses approaches indicated an overall decline of at least 20 % during 1965–2012. A clear regional pattern
39
40 527 could not be found.

41 528 42 43 44 529 **3.3 Correlation of HM concentrations in moss and organic surface soil sampled across Norway 1990-2010**

45
46 530
47
48 531 Basic descriptive statistical measures (number of sites, minimum, maximum, median) for the concentrations of As, Cd, Cr,
49
50 532 Cu, Fe, Hg, Ni, Pb, Sb, Ti, V, and Zn in moss collected in 1990, 1995, 2000, 2005, and 2010 as well as for natural surface
51
52 533 soil specimen sampled in 1995 and 2005 were computed. For Cd, Hg and Pb, the highest medians as well as maximum
53
54 534 values in moss can be observed in the 1990 survey. Between 1990 and 2010 Pb concentrations in moss decreased from 9.3
55
56 535 µg g⁻¹ in 1990 to 1.5 µg g⁻¹ in 2010. The median concentration of Hg in 2010 (0.064 µg / g) was almost the same as in 1990
57
58 536 and 1995 (0.068 µg g⁻¹). The highest median concentrations in soil were calculated for Cd and Pb in 1995. In case of Pb,
59
60 537 there was a slight but significant decrease over time reaching from 34.6 µg g⁻¹ in 1995 to 25.8 µg g⁻¹ in 2005 (α = 0.01). The

538 concentrations of Cd, Hg, and Pb in moss significantly decreased over time, except for Cd comparing 1990 / 1995, 1990 /
1 2005, and 2000 / 2010 and for Hg 1990 / 1995, 1990 / 2010, 1995 / 2010, and 2000 / 2005. The concentrations of As, Cr,
2 3
4 540 Cu, Fe, Ni, Ti, Sb, V, and Zn (for details see Meyer et al. 2015 b) in moss mostly showed significant slight decrease across
5
6 541 the surveys. However, this trend is not significant for As 1990 / 1995, 2000 / 2005, 2000 / 2010, and 2005 / 2010; for Cr 2005 /
7 542 / 2010; for Cu 1990 / 1995 and 2000 / 2010; for Fe 1995 / 2000 and 2005 / 2010; for Ni 1990 / 1995 and 2000 / 2010; for Sb
8 9
10 543 2005 / 2010; for V 1990 / 1995, 2000 / 2010, and 2005 / 2010; and for Zn 1990 / 2005, 2000 / 2005, 2000 / 2010, and 2005 /
11 544 2010. The mean HM concentrations in natural surface soil slightly decrease significantly between 1995 and 2005, except for
12 545 As ($p = 0.78$, not significant (n.s.)), Cd ($p = 0.21$, n.s.), Cu ($p = 0.05$, n.s.), Ti ($p = 0.67$, n.s.), and V ($p = 0.04$, n.s.).
13
14
15
16 546
17
18 547 Spearman correlation analysis revealed significant statistical associations between measured HM concentrations in moss
19
20 548 and soil. Highest coefficients were computed for Pb (r_s around 0.8), followed by Cd ($r_s \approx 0.5$). Correlations between Hg
21
22 549 concentrations in moss and soil samples ranged between $r_s \approx 0.3$ and $r_s \approx 0.4$. The Spearman correlation coefficients
23
24 550 between the measured Cd, Hg and Pb concentration in moss and the respective Kriging estimated concentrations in soil and
25
26 551 between the measured Cd, Hg and Pb concentration in soil and the respective Kriging estimated concentration in moss show
27
28 552 the same tendency and are slightly higher as those derived only from measured values. The highest coefficients were found
29
30 553 for Pb ($0.81 \leq r_s \leq 0.88$), followed by Cd ($0.65 \leq r_s \leq 0.78$) and Hg ($0.35 \leq r_s \leq 0.39$). These findings together with the results
31
32 554 from cross-validation corroborate the spatial validity of surface estimations and of the surveys (Nickel et al. 2014).
33
34 555
35
36 556 Based on this, the correlation of measured Cd, Hg and Pb concentrations either in moss and in soil samples and potential
37
38 557 influencing factors such as sea spray effect, elevation above sea level, precipitation, land use, population density, soil texture
39
40 558 (percentage of clay, silt and sand) and modelled total atmospheric deposition of Cd, Hg and Pb (EMEP) are of special
41
42 559 interest (for details see Meyer et al. 2014). Regarding the element concentrations in moss, the modelled deposition values by
43
44 560 far showed the highest significant ($\alpha = 0.01$) correlations especially for Pb ($0.69 \leq r_s \leq 0.82$ for all years) and Cd ($0.61 \leq$
45
46 561 $r_s \leq 0.73$ for all years). Like in the case of natural surface soil, for Hg, the weakest correlations among all three elements
47
48 562 were identified ($0.26 \leq r_s \leq 0.46$ for all years). The same tendency can be observed regarding the statistical association of
49
50 563 the metal concentrations in moss and the urban land use percentages within 1- and 5-km radiuses. Here, the corresponding
51
52 564 coefficients are lower ($r_{s\ max} < \approx 0.5$) in all cases. The percentages of agriculture land use ($r_{s\ max} \approx 0.2$ for Pb in 1995) and
53
54 565 forest areas ($r_{s\ max} \approx 0.3$ for Cd in 1995) showed generally low and mostly non-significant correlations with the HM
55
56 566 concentrations in moss. For agricultural, forested and urban land use, the highest associations were identified within a radius
57
58 567 of 5 km. Regarding elevation, mostly low negative ($r_s < \approx -0.3$) and in six cases non-significant coefficients were computed.
59
60
61
62
63
64
65

568 Similar holds true for the distance between monitoring sites and the sea: Only for Hg, a weak significant signal for all
1
2 569 campaigns except for 2010 was observed.

3
4 570
5
6 571 In a similar way as for the HM concentrations in moss, HM concentrations in soil samples were preferentially correlated with
7
8 572 atmospheric HM deposition (Pb $0.69 \leq r_s \leq 0.82$, Cd $0.61 \leq r_s \leq 0.73$, Hg $r_s = 0.16$). Population density was significantly
9
10 573 correlated with the three HM in focus (Pb $0.40 \leq r_s \leq 0.45$, Cd $0.23 \leq r_s \leq 0.25$, Hg $r_s = 0.28$). Urban land use within a 5 km
11
12 574 radius around sampling sites was most strongly, but low, correlated with concentrations of Cd ($r_s = 0.2$ in 2005) and Pb ($r_s =$
13
14 575 0.29 in 1995, 2005).

15
16 576
17
18 577 Multivariate relations between HM concentrations in moss and soil specimen and environmental characteristics were
19
20 578 investigated by 4 approaches: CART computations including the HM concentrations in soil as potential environmental factor
21
22 579 (approaches 1 and 3 described in [Section 2.2.3](#)) proved that the geostatistically estimated HM concentrations in natural
23
24 580 surface soil was the most powerful predictor for measured concentrations of Cd, Hg and Pb in moss. In computations which
25
26 581 did not include the HM concentrations in soil (approach 2, 4 described in [Section 2.2.3](#)), the modelled atmospheric HM
27
28 582 deposition 'replaced' the HM concentrations in soil as mostly influencing Cd, Hg and Pb concentrations in moss. Thus, moss
29
30 583 and soil indicate the same phenomenon (Meyer et al. 2015 b; Steinnes et al. 2011).

31
32 584
33
34 585 For As, Cu, Sb, and V, the population density was the most powerful predictor between 1990 and 2010 (approach 2, Meyer
35
36 586 et al. 2015 b). Following Weckwerth (2001), the use of Sb in brake pads of motor vehicles and the intensified use of
37
38 587 automobiles in densely populated areas is probably the main reason for higher Sb levels in moss. Considering the maximum
39
40 588 value of Sb, there was an increase of Sb in both moss (1990: $0.6 \mu\text{g g}^{-1}$, 2010: $1.2 \mu\text{g g}^{-1}$) and in natural surface soil from 5.4
41
42 589 $\mu\text{g g}^{-1}$ in 1995 to $24.8 \mu\text{g g}^{-1}$ in 2005. The reduction of Sb emissions due to combustion processes in recent years was
43
44 590 compensated by an increased number of motor vehicles (Steinnes et al. 2011). V, mainly emitted by combustion of fuel oils,
45
46 591 only showed a small reduction of concentration in moss and natural surface soil with time (Meyer et al. 2015 b). Cu increased
47
48 592 in, both, moss and natural surface soil from 1990 to 2010. The results of the CART analyses correspond to Steinnes et al.
49
50 593 (2011) associating high population densities with increasing industrial activities. For Cr and Fe, the percentages of urban
51
52 594 areas 5 km around the moss sampling sites is the predictor with the strongest association to the respective HM
53
54 595 concentrations in moss – the higher the population density, the higher the concentrations in moss. Both the Fe and the Cr
55
56 596 concentrations in moss increased over time, whereby Fe is mainly associated with mineral dust blown by the wind and Cr
57
58 597 with domestic sources (Steinnes et al. 2011). The highest Cr and Ni concentrations collected across are respectively 6 and
59
60 598 20 times higher than the median concentration values of European countries and probably originated from industrial

599 emission of ferrochromium metallurgy, mine industry and the wind blowing soil dust from Cr and Fe-Ni mineral open slag
1
2 600 dumps (Qarri et al. 2013).

3
4 601

5
6 602 The case study showed a decrease of HM concentrations in both moss and soil specimen collected across Norway.

7
8 603 However, in case of moss samples the decrease is more pronounced and statistically significant. The spatial patterns of Cd

9
10 604 and Pb concentrations in moss and soil specimens in 1995 and 2005 are similar. For Cd and Pb, the spatial differentiation of

11
12 605 concentrations in moss is higher than in soil, while the opposite is true for Hg. Response times, especially of Pb

13
14 606 concentration in soil, appear to be generally delayed compared to those of moss. Thus, risk assessments relying on

15
16 607 terrestrial moss sampled across drainage basins help monitoring whether emission reductions result in decreasing

17
18 608 atmospheric deposition for protecting terrestrial and aquatic sediments and biota. The integration of (organic) surface soil

19
20 609 samples seems to be important for assessing effects of atmospheric deposition on compartments that respond more slowly

21
22 610 than moss. At ICP Integrated Monitoring sites, the decline of Cd and Pb in the humus and top soil layers was accompanied

23
24 611 by an increase in deeper soil layers in recent decades. Hg concentrations in deeper soil layers have also increased,

25
26 612 demonstrating continued soil accumulation of heavy metals (WGE 2015).

27
28 613

29
30 614 Sediments result from chemical and physical weathering of rocks, subsequent transport by wind, water, mass movement or

31
32 615 ice and, finally, accumulation of weathering products on land surfaces or in aquatic ecosystems such as lakes, rivers, and

33
34 616 oceans (Jenny 1941 / 1994; White et al. 1998). Their biological, chemical and physical condition is mainly influenced by

35
36 617 respective characteristics of their catchment basins including not only their soil and vegetation coverage and land use but

37
38 618 also atmospheric deposition (Baron et al. 2013). That is why a catchment-based approach for monitoring and protection of

39
40 619 aquatic ecosystems is needed (Breuer et al. 2008; Sharpley et al. 2015; Wolanski et al. 2004). Consequently, the European

41
42 620 Water Framework Directive (WFD, Directive 2000 / 60 / EC) aims at protecting aquatic systems including their sediments by

43
44 621 protecting their drainage basins (Noges et al. 2006; Reible and Lanczos 2006). The WFD aims to reach a "good ecological

45
46 622 status" of aquatic ecosystems by water management at the river basin level. Similarly to concepts of ecological integrity and

47
48 623 ecosystem health, "ecological status" means the quality of the structure and functioning of aquatic ecosystems and is to be

49
50 624 assessed by biological, hydromorphological, and physico-chemical characteristics and evaluated using a scale graded by

51
52 625 different deviations from the reference condition associated with no or very low anthropogenic pressure (Noges et al. 2006).

53
54 626 To this end, the implementation of the WFD needs monitoring data from the above ICPs.

55
56 627

57
58 628 Atmospheric deposition is one of the pressures affecting directly and, via surface and sub-surface runoff, indirectly the

59
60 629 chemical condition of waters and their sediments (Driscoll et al. 2007; EEA 2014; Eisele and Leibundgut 2002; Gassama and

61
62
63
64
65

630 Violette 2012; Langedal et al. 1998; Lepori and Keck 2012; Moldan et al. 2006; Oulehle et al. 2013; Prechtel et al. 2001;
1 Rogora et al. 2012; Waller et al. 2012). Even if more than 90 % of the Quaternary¹ deposits in Norway have been
2
3
4 632 transported and deposited offshore large areas are covered with at least a thin sediment cover (Olsen et al. 2013):
5
6 633 Generally, Norway has large areas of exposed bedrock or bedrock with a thin cover of Quaternary sediments. A thin layer of
7
8 634 sediments enhances the vulnerability to acidification on the one hand and decreases the time for responding to changing
9
10 635 atmospheric deposition (Skjelkvåle and de Wit 2011). The South-eastern parts of Norway, the Jæren area in Southwest
11
12 636 Norway and Finnmarksvidda in northern Norway have extended areas with a continuous cover of sediments. The average
13
14 637 thickness of the till deposits which cover about 25 % of the mainland of Norway is about 6 m. Brown trout populations in
15
16 638 thousands of lakes and native salmon populations from seven major rivers, such as the Tovdal River, got extinct due to
17
18 639 atmospheric deposition of acidic pollutants and HM toxicity. A survey conducted in the 1990s in Fenno-Scandia documented
19
20 640 that acidification has impaired fish populations at least 10 000 lakes (Holen et al. 2013). Simultaneous surveys, conducted
21
22 641 1995 in Norway, proved the same geographic patterns of HM concentrations in moss, soils (humic layers), lake sediments,
23
24 642 and surface waters (Skjelkvåle et al. 2006).

25
26 643
27
28 644 In the lake Dümmer region in North-western Germany, where cyanobacteria regularly causes severe ecological problems,
29
30 645 the atmospheric N deposition amounted to roughly 21 kg N ha⁻¹ a⁻¹ as estimated from moss specimens sampled in 2005.
31
32 646 This yields a direct yearly input to Lake Dümmer of about 25 t N. The N deposition into the catchment area of Lake Dümmer
33
34 647 is, taking the moss estimates, about 738 t a⁻¹ and 1107 t a⁻¹ according to deposition modelling (Holy et al. 2011). As holds
35
36 648 true for the Dümmer catchment area, sediments spatially dominate the drainage basins and the territory of Germany (357387
37
38 649 km²): Limnic sediments cover 1 %, magmatic and metamorphic rocks each 4 % as well as unconsolidated sediments 55 %
39
40 650 and 36 % consolidated sediments (Stegger 2015 based on the Hydrologic Atlas of Germany, table 1.5 'lithology', BMU
41
42 651 2003). This sedimentary coverage is exposed to environmental contamination through atmospheric deposition.

43
44 652

45 46 653 3.4 Variation of N concentrations in moss at site level due to canopy drip effects

47
48 654
49
50 655 Considering the N concentration in moss collected across North-Western Germany (Kluge et al. 2013; Meyer et al. 2015 a,
51
52 656 2015 b), the average concentration at sites with canopy drip was both significantly higher in 2013 (mean: 2.50 % in dry
53
54 657 weight which, applying a regression model, corresponds to 31.3 kg ha⁻¹ a⁻¹) compared to 2012 (2.27 %, 26.4 kg ha⁻¹ a⁻¹) and
55
56 658 significantly higher compared to the N concentration in moss sampled at adjacent sites without canopy drip (mean 2012:

59
60
61
62
63
64
65
¹ The Quaternary Period is the current period in the geologic time scale of the International Commission on Stratigraphy. It is divided into two epochs: the Pleistocene (ca. 2.6 million years ago to ca. 12 thousand years ago) and the Holocene (ca. 12 thousand years ago to today).

659 1.11 %, 7.3 kg ha⁻¹ a⁻¹, 2013: 1.39 %, 10.9 kg ha⁻¹ a⁻¹). The maximum within the forest stands accounted for ~ 56 kg ha⁻¹ a⁻¹
1
2 660 in 2012 and 43 kg ha⁻¹ a⁻¹ in 2013. Compared to N values in mosses collected across in 2005, there was a decline of the
3
4 661 average N deposition by 2.4 kg N ha⁻¹ a⁻¹ in open fields. However, the average N deposition within forests stands in 2012
5
6 662 remained nearly the same since 2004 (29 kg N ha⁻¹ a⁻¹). The atmospheric N deposition derived from the N concentration in
7
8 663 moss averaged for 2012 and 2013 ranged between the minimum and maximum critical load value at 21 of 30 sites with
9
10 664 canopy drip (70 %) and exceeded the maximum critical load value at 30 % (Meyer et al. 2015 a).

11 665
12
13
14 666 The deposition values estimated from the moss concentrations in North-western lowland of Germany are rather high
15
16 667 compared to those reported for the Bavarian Forest site within the ICP Integrated Monitoring. Here, the bulk deposition
17
18 668 collected during 2003 -2012 in beech and spruce forests located at 825 m a.s.l. and 720 m a.s.l. amounted to 10 kg ha⁻¹ a⁻¹.
19
20 669 Deposition values collected under beech and spruce canopies did not differ significantly, neither from each other nor from
21
22 670 open land sites. Averaged modelled values for total deposition were 10-13 kg ha⁻¹ a⁻¹ (beech) and 11-17 kg ha⁻¹ a⁻¹, and the
23
24 671 maximum total deposition 15 kg ha⁻¹ a⁻¹ (beech) and 22 kg ha⁻¹ a⁻¹ (spruce) (Beudert and Breit 2014).

25 672
26
27
28 673 Ranking interacting factors associated with N concentration in moss sampled during 2012 and 2013 in North-Western
29
30 674 Germany by use of CART confirmed the canopy drip to be the factor most associated to the N concentration in moss
31
32 675 integrating all site-specific factors (sampling site category: site with / without canopy drip; moss species: *Pleurozium*
33
34 676 *schreberi*, *Scleropodium purum*; sampling year: 2012, 2013; tree height; distances to emission sources: traffic, industry,
35
36 677 agriculture; percentages of urban, agricultural and forested areas in 1 km, 5 km, 10 km and 25 km around the sampling sites;
37
38 678 population density; precipitation; distance to North Sea). The CART model presented explains 82 % of the variance in the
39
40 679 data set comprising 112 measurements. This result was corroborated by a CART and Random Forest modelling based on
41
42 680 the merged data sets published by Harmens et al (2015) and Meyer et al. (2015 b). Both models explained 71 % and 77 % of
43
44 681 the variance (Meyer et al. 2015 b).

45 682
46
47
48 683 Merging the data from above mentioned sites sampled during 2012 and 2013 in North-Western Germany (Meyer et al. 2015
49
50 684 a) with data from moss collected across Europe (Harmens et al. 2014) yielded an average N content of 11.9 mg g⁻¹ at open
51
52 685 sites and by 20.0 mg g⁻¹ at throughfall sites. Modelled atmospheric deposition rates were also higher at throughfall
53
54 686 (18.0 kg ha⁻¹ a⁻¹) compared to open sites (15.4 kg ha⁻¹ a⁻¹). Taking the different countries into account, the highest average N
55
56 687 content measured in *moss* at open sites was 13.9 mg g⁻¹ in Slovenia. Germany showed the second highest average N
57
58 688 content in moss with 12.6 mg g⁻¹ followed by Austria (12.2 mg g⁻¹), Switzerland (12.0 mg g⁻¹) and Finland (8.2 mg g⁻¹).
59
60 689 Regarding the average values at throughfall sites, Germany had by far the highest average N content (22.5 mg g⁻¹) followed
61
62
63
64
65

690 by France (13.5 mg g⁻¹) and Spain (11.9 mg g⁻¹). The overall average N content at sampling locations inside the peripheral
1 tree canopy was 20.0 mg g⁻¹. Thus, the average N content measured in moss deviated from the total average value by 11 %
2
3
4 692 (Germany), -48 % (France) and -68 % (Spain) (Meyer et al. 2015 b). On the whole, these findings are in line with NH₄⁺ and
5
6 693 NO₃⁻ measurements in bulk deposition (Harmens et al. 2015; Meyer et al. 2015 b): The highest average NH₄⁺ concentration
7
8 694 was measured at open sites in Germany followed by Austria, Slovenia, Switzerland and Finland. Under canopy, in Germany
9
10 695 again the highest NH₄⁺ and NO₃⁻ concentrations in bulk deposition were determined. In France, the NH₄⁺ and NO₃⁻
11
12 696 concentrations were second highest followed by Spain.

13
14 697
15
16 698 Often either element concentrations are measured at sites below canopies *or* beyond them and not at both, open *and*
17
18 699 throughfall sites as conducted by Skudnik et al. (2014, 2015) and Meyer et al. (2015 a, 2015 b). These studies yielded
19
20 700 factors calculated by regression analysis enabling to estimate open site values from measured throughfall data and vice
21
22 701 versa. Measured and estimated N contents neither at open sites nor at throughfall sites differed significantly (p: 0.81,
23
24 702 Wilcoxon signed-rank test).

25
26 703

27 28 29 704 4 Conclusions

30
31 705
32
33 706 Pollutants emitted into the atmosphere are deposited at Earth's surface where they accumulate in biota and sediments of
34
35 707 terrestrial and of aquatic ecosystems. In Germany, most of the pollutant load of aquatic systems is derived from atmospheric
36
37 708 deposition. Thus, assessing risks for aquatic sediments necessarily needs spatial valid information on atmospheric
38
39 709 deposition onto land surfaces of drainage basins (Böhm et al. 2000; Fuchs et al. 2010). There, atmospheric deposition can
40
41 710 be collected by technical devices (Hansen et al. 2013) and, as demonstrated in this article, by moss. In contrast to
42
43 711 measurements with technical deposition samplers moss surveys allow covering a broad range of spatial scales with the
44
45 712 same method in a high spatial density. From the investigations presented can be concluded that the European moss surveys
46
47 713 comprise enough sample sites for reliable statistics for Europe as a whole, single countries and – with specific restrictions -
48
49 714 ecologically defined land classes covering Europe (methods [Sections 2.2.1](#), results: [Section 3.2](#)). The results for the
50
51 715 minimum sample size needed on the landscape level in some cases might give reason to discuss the number of sampling
52
53 716 sites needed depending on the aim of the analysis to be done. Pesch et al. (2008) developed a methodology to optimize the
54
55 717 German moss monitoring network without reduction of statistical reliability. Accordingly, the German moss survey network for
56
57 718 2005 was designed and will again be re-structured for the campaign 2016. Ecological land classifications such as ELCE are
58
59 719 important on regional level because usually ecological maps are not synchronized between countries. However, on small
60

720 scale, similar maps as ELCE₄₀ could be less accurate than national ecological or nature protection maps and, because of
1
2 721 this, countries are encouraged to do similar analysis also on the country level for regional and local important ecological
3
4 722 classes. Alternatively, to this end ELCE versions with up to 230 classes are available and could be used.

5
6 723
7
8 724 Undoubtedly, the current spatial resolution of the European moss survey yields data at unrivalled high spatial density enabling
9
10 725 to detect spatial valid long-term trends of HM and N atmospheric deposition of HM (1990-2010) and N (2005-2010 (HM)
11
12 726 (methods Sections 2.1.1 and 2.2.2, results: Section 3.3). Further, HM concentrations in moss were proved correlated with
13
14 727 HM concentrations in organic surface soil and, thus, due to leaching of HM from soil, indicate a potential risk for aquatic
15
16 728 ecosystems and their sediments (methods Sections 2.1.2 and 2.2.3, results Section 3.4). Even if we observed a (minor)
17
18 729 decline of Pb in the humic surface layer from 1995 to 2005, organic-rich surface soils in Norway and elsewhere have
19
20 730 accumulated metals from air pollution over centuries, and some of these metals, Pb in particular, are only slowly released to
21
22 731 adjacent surface waters as they accumulate in deeper soil layers. Others, such as Zn and Cd, are strongly accumulated by
23
24 732 plant roots and hence retained in the terrestrial ecosystem for a long time. Thus, the relations between these metals in
25
26 733 surface soil and surface water / sediment are likely to be much weaker than correspondingly for moss samples - if evident at
27
28 734 all. Additionally, the investigation corroborated that the moss biomonitoring technique seems to be able to reliably detect *site-*
29
30 735 specific variance due to the filter effect of vegetation canopies (methods Sections 2.1.3 and 2.2.4, results Section 3.5).
31
32 736 Further validation of this issue will be the focus of the upcoming moss survey in Germany 2016.

33
34 737
35
36 738 These findings are of relevance for the risk assessment of aquatic sediments, since, like in terrestrial ecosystems, sediments
37
38 739 are sinks for atmospheric deposition in aquatic systems. Under changing environmental conditions such as pH and oxidation-
39
40 740 reduction potential at the interface between the sediment and the water body HM may be desorbed from the sediment and
41
42 741 released to the aqueous phase (Förstner 1995; Soares et al. 1999). The accumulation of potentially hazardous substances
43
44 742 such as HM in an organism relative to its level in the ambient medium (bioaccumulation) is of major environmental concern,
45
46 743 especially when referring to aquatic ecosystems (Schäfer et al. 2015). Their drainage areas capture and spatially concentrate
47
48 744 materials derived from large terrestrial areas and even larger areas by atmospheric long-range transport and subsequent
49
50 745 deposition. Atmospheric transport and deposition of global emissions may complicate the response of HM such as Hg levels
51
52 746 in fish to regulation and remediation (Bhavsar et al. 2010; Gandhi et al. 2014). Taking Hg as an example, the response of
53
54 747 concentrations in freshwater fish to changes in anthropogenic emissions depends on several factors affecting Hg cycling and
55
56 748 bioaccumulation such as drainage basin characteristics causing considerable variation of transferring atmospheric deposition
57
58 749 to fish (Akerblom et al. 2014). Therefore, the protection of aquatic ecosystem including their sediments needs the spatially
59
60 750 differentiated characterisation of watersheds by mapping atmospheric deposition (moss, technical samplers, modelling), land

751 use (Corine: EU and national level), soils (nation-wide soil maps, FAO soil map on European level), ecoregions (Pardo et al.
1 2015; Schröder et al. 2007, 2013, 2014) and ecosystem types coverage based on structures and functions (Schröder et al.
2 2015). In this context, moss data could be used to estimate the atmospheric input of pollutants into sediments of catchment
3
4 753 basins and aquatic ecosystems and, thus, contribute to risk assessment in context with the WFD. For this purpose,
5
6 754 comparisons between moss data and results from numeric modelling of atmospheric deposition (Nickel et al. 2015 b) as a
7
8 755 basis for dealing with uncertainties in N and HM balances are of great importance.

Table 3. Decline in the average median HM and N concentrations in moss specimens since the start of the European moss survey in 1990a and since the survey in 2005b (Harmens et al. 2013 c, 2015)

Element	Decline since 1990 ^c (%)	Decline since 2005 (%)	Element	Decline since 1990 ^c (%)	Decline since 2005 (%)
Aluminium	n.a.	28	Lead	77	36
Antimony	n.a.	23	Mercury	14	20
Arsenic	21	25	Nickel	33	12
Cadmium	51	7	Vanadium	57	27
Chromium	43	23	Zinc	34	7
Copper	11	6			
Iron	27	15	Nitrogen	n.a.	5

^a Based on data from countries that participated in at least four out of five surveys. For As countries were included that participated in four survey years since 1995. For Hg some countries were included that had data for three out of four surveys since 1995.

^b Based on data from countries that participated in both survey years.

^c Decline since 1995 for As and Hg.

n.a. = not available

Figure S1. Map of Ecological Land Classes of Europe (ELCE₄₀) (Hornsmann et al. 2008) (Legend:

Table S1)

Table S1. Legend of the map on Ecological Land Classes of Europe (ELCE₄₀) (Hornsmann et al. 2008)

ELCE Code	Main distribution	Area [km ²]
B_1	Western and northern Scandinavia, northwest Russia	178800
B_2	The Alps, Iceland, northwest Russia	311400
C_0	The Alps, Iceland, western and northern Scandinavia, Kola Peninsula, northwest Russia, Caucasus	321800
D_7	Scandinavia, northwest Russia	185700
D_8	Kola Peninsula, northwest Russia	287800
D_10	Russia	96700
D_13	The Alps, dispersed small areas in eastern and southeast Europe	377500
D_14	Baltic States, Belarus, western Russia	537900
D_17	Scandinavia, western Russia	336000
D_18	Southern Scandinavia, northern Baltic States	150500
D_19	Southern/central Finland, Norway	227100
D_21	Northwest Russia	92800
D_22	Sweden, northwest Russia	534000
F1_1	Poland, northwest Ukraine	162000
F1_2	Ireland, Great Britain, western and central Europe	431000
F2_5	Southern Baltic States, eastern Poland, western and southwest Ukraine	231400
F2_6	Central Europe, eastern and southeast Europe	345200
F3_1	Germany, northwest Poland, Czech Republic, northern Austria, Slovenia, the Balkans	154800
F3_2	Western Europe (including northern Spain, France, Benelux countries, western Germany), Denmark	225100
F4_1	Southeast Great Britain, southeast Denmark, northeast Germany, northwest Poland	79900
F4_2	Western/central and southern Europe (including southern Great Britain, eastern France, southern Belgium, Luxembourg, the Alps, Italy), eastern and southeast Europe (including the Carpathian Mountains, the Balkans)	483300
G1_0	Italy, southeast Europe	303000
G2_0	Iberian Peninsula, southern and southeast Europe	296200
J_2	Iberian Peninsula, coastal areas by the Mediterranean Sea	438200
L_2	Eastern Europe (Hungary, Romania, Moldova, Ukraine, Russia)	352500
M_5	Eastern Ukraine, Southwest Russia, Caucasus	233800
M_6	Eastern Romania, southern Ukraine	131100
S_0	Northern parts of Europe (including parts of Iceland, Ireland, Great Britain, Scandinavia, northwest Russia, the Baltic states and Belarus)	271600
U_1	Dispersed small areas within a stripe reaching from Ireland via central Europe and the Byelorussian-Ukrainian borderline to Russia	199300
U_2	Dispersed small areas in southern Europe reaching from the Iberian Peninsula via southeast Europe including e.g. the Balkans, the Carpathians, Greece and northern Turkey to southwest Russia	239900
Others	Southwest Russia, Georgia, Azerbaijan, Armenia and further small areas all across Europe	347800

ELCE = 30 Ecological land classes and other ELCE which were summarized to one class ("Others");
