# Hydrological Summary for the United Kingdom <br> <br> General 

 <br> <br> General}

April was a cool and wet month, with some unsettled weather and a very wintry spell in the final week. All regions were colder than average, and nationally the monthly temperature was $0.9^{\circ} \mathrm{C}$ below the long-term average (although not exceptional; 2012 and 2013 were colder). It was also wetter than average in most regions, although not significantly so except in some isolated areas, while in south-west Britain it was relatively dry. The snowfall in the final week was unusually widespread for late April, while in northern Britain some seasonally significant accumulations occurred even at low altitudes. Occasional periods of heavy rainfall triggered localised surface water flooding and modest river flow spates, but overall river flows for April were largely in the normal range or moderately above. Groundwater levels receded at the majority of sites, but remained in the normal range or slightly above for April, except in northern England and southern Scotland where exceptional levels persisted following the wet winter. Reservoir levels were just above average at the national scale, and above $90 \%$ of capacity in all but a few northern impoundments, where they were only slightly below. Overall, the water resources outlook for the remainder of spring and summer 2016 is healthy.

## Rainfall

April started unsettled, as westerly airflows brought frequent showers and some persistent frontal rainfall to northern and western areas (with 104.6 mm registered on Skye on the $2^{\text {nd }}$ ). An easterly airflow became established in the second week, but unsettled conditions continued; around mid-month, an array of frontal systems, including embedded convective cells, brought thunderstorms and intense rainfall to parts of central and eastern England (with 41 mm in Hull on the $12^{\text {th }}$ ), with localised surface water flooding bringing some transport disruption (e.g. in the Thames Valley on the $15^{\text {th }}$ ). The second half of April was dominated by a northerly airstream, bringing cold and showery conditions, with the final week seeing widespread wintry showers and significant late-spring snowfall; on the $28^{\text {th }} / 29^{\text {th }}$ persistent snowfall resulted in some transport disruption in Scotland and northern England. April rainfall totals were above average at the national scale ( $123 \%$ of average for the UK as a whole) and for a majority of regions. The highest totals were in parts of northern Britain, East Anglia and central western England; localised pockets of $>150 \%$ were widespread. North-east Scotland as a whole received $157 \%$ of average, with $>170 \%$ along parts of the coast. In contrast, south-west England saw 74\% of average, while south Wales and parts of East Sussex and Kent were also drier than average, as were isolated parts of western Scotland. Generally, the first two months of spring has seen a reversal of the typical rainfall gradient for the UK: parts of western Scotland saw less than 70\% of average over this timeframe, while parts of eastern England received over $150 \%$. This contrasts markedly with the preceding winter which, due to a predominance of westerly airflows, saw an exaggeration of the typical north-west/south-east rainfall gradient.

## River flows

River flows were above average entering April in most index rivers in the north and west, and many rivers saw spates continue in the first week in response to the unsettled weather conditions. Intense rainfall mid-month triggered rapid flow increases in some responsive catchments in central and south-east England. Overall, however, despite the unsettled complexion to the first half of the month, there were few fluvial flood alerts - in stark contrast to previous months - and there were no notable peak flows reported from across the network of index catchments. Although interrupted by spates, the typical pattern of seasonal river flow recession can be discerned at a majority of sites, particularly through the latter half of the month
(and throughout April in south-west Britain), although the last week saw further flow responses in parts of northern Britain. Average river flows for April were in the normal range or above, with the highest monthly flows in central and eastern England (e.g. the Colne, Derwent), north Wales and the Welsh borders (e.g. the Severn, Welsh Dee), areas that received above average rainfall over the last two months. In many groundwater-fed rivers (e.g. the Coln and the Itchen) elevated flows also reflect above average rainfall for 2016 so far. While above normal flows were registered on the Nith and the Cree in south-west Scotland, flows in north-west Scotland were below average, although all but the Nevis were within the normal range. Similarly, in south-west Britain, river flows were below average but remained in the normal range. For the last two months combined, runoff accumulations show a similar spatial pattern to April. Over longer timeframes, runoff accumulations are largely well above average and exceptional in the north and west, reflecting the wet winter.

## Groundwater

Soil moisture deficits increased through April, but were still modest for the time of year, and well below the long-term mean across the major aquifer areas (reflecting the above average rainfall and cooler temperatures of the spring so far). In the Chalk, groundwater levels were in the normal range or above at all index sites. In slower responding boreholes, levels continued to rise from Oxfordshire to Lincolnshire, but the seasonal recession that started in March continued in both Yorkshire (with Wetwang falling from exceptionally high to notably high) and across southern England. Throughout the Permo-Triassic sandstones, levels continued to fall or were stable, with the exception of Heathlanes where there was a moderate increase. In south-west England, the Midlands and north Wales levels remained in the normal range or just above, but in north-west England they were still notably high at Skirwith, and at Newbridge in southern Scotland they were exceptionally high for the time of year. In the Jurassic limestones, levels rose slightly and remained in the normal range at New Red Lion, but fell from exceptionally high (caused by a response to the very high March rainfall in this area) to above average at Ampney Crucis (Cotswolds). Levels remained very high in the Magnesian Limestone, with a second consecutive record monthly maximum recorded at Brick House Farm. Levels in the Carboniferous Limestone fell during April but remained in the normal range in both south Wales and at Alstonefield in Derbyshire.

## Met Office 3-month outlook Updated: April 2016

Predictions for UK precipitation show a slight increase in the probability of above-average rainfall for May. For May-June-July as a whole, the forecast for UK precipitation suggests that the chances of above- and below-average rainfall are fairly balanced. The probability that UK precipitation for May-June-July will fall into the driest of our five categories is between $20 \%$ and $25 \%$ and the probability that it will fall into the wettest of our five categories is $25 \%$ (the 1981-2010 probability for each of these categories is $20 \%$ ).

The complete version of the 3-month outlook may be found at: http://www.metoffice.gov.uk/publicsector/contingency-planners This outlook is updated towards the end of each calendar month.

The latest shorter-range forecasts, covering the upcoming 30 days, can be accessed via:
http://www.metoffice.gov.uk/weather/uk/uk forecast weather.html These forecasts are updated very frequently

## River flow . . . River flow

Based on ranking of the monthly flow*

## River flows

*Comparisons based on percentage flows alone can be misleading. A given percentage flow can represent extreme drought conditions in permeable catchments where flow patterns are relatively stable but be well within the normal range in impermeable catchments where the natural variation in flows is much greater. Note: the period of record on which these percentages are based varies from station to station. Percentages may be omitted where flows are under review.

## River flow . . . River flow

## River flow hydrographs

The river flow hydrographs show the daily mean flows together with the maximum and minimum daily flows prior to May 2015 (shown by the shaded areas). Daily flows falling outside the maximum/minimum range are indicated where the bold trace enters the shaded areas. Mean daily flows are shown as the dashed line.

## River flow . . . River flow

## Groundwater... Groundwater

Groundwater levels normally rise and fall with the seasons, reaching a peak in the spring following replenishment through the winter (when evaporation losses are low and soil moist). They decline through the summer and early autumn. This seasonal variation is much reduced when the aquifer is confined below overlying impermeable strata. The monthly mean and the highest and lowest levels recorded for each month are displayed in a similar style to the river flow hydrographs. Note that most groundwater levels are not measured continuously and, for some index wells, the greater frequency of contemporary measurements may, in itself, contribute to an increased range of variation. The latest recorded levels are listed overleaf.

## Groundwater... Groundwater

## Groundwater levels - April 2016

The calculation of ranking has been modified from that used in summaries published prior to October 2012. It is now based on a comparison between the most recent level and levels for the same date during previous years of record. Where appropriate, levels for earlier years may have been interpolated. The rankings are designed as a qualitative indicator, and ranks at extreme levels, and when levels are changing rapidly, need to be interpreted with caution.

[^1]- denotes reservoir groups

[^2]Details of the individual reservoirs in each of the groupings listed above are available on request. The percentages given in the Average and Minimum storage columns relate to the 1988-2012 period except for West of Scotland and Northern Ireland where data commence in the mid-1990s. In some gravity-fed reservoirs (e.g. Clywedog) stocks are kept below capacity during the winter to provide scope for flood attenuation purposes. Monthly figures may be artificially low due to routine maintenance or turbidity effects in feeder rivers.

## Location map... Location map

## NHMP

The National Hydrological Monitoring Programme (NHMP) was started in 1988 and is undertaken jointly by the Centre for Ecology \& Hydrology (CEH) and the British Geological Survey (BGS). The NHMP aims to provide an authoritative voice on hydrological conditions throughout the UK, to place them in a historical context and, over time, identify and interpret any emerging hydrological trends. Hydrological analysis and interpretation within the Programme is based on the data holdings of the National River Flow Archive (NRFA; maintained by CEH) and National Groundwater Level Archive (NGLA; maintained by BGS), including rainfall, river flows, borehole levels, and reservoir stocks.

## Data Sources

The NHMP depends on the active cooperation of many data suppliers. This cooperation is gratefully acknowledged.
River flow and groundwater level data are provided by the Environment Agency (EA), Natural Resources Wales Cyfoeth Naturiol Cymru (NRW), the Scottish Environment Protection Agency (SEPA) and, for Northern Ireland, the Rivers Agency and the Northern Ireland Environment Agency. In all cases the data are subject to revision following validation (high flow and low flow data in particular may be subject to significant revision).

Details of reservoir stocks are provided by the Water Service Companies, the EA, Scottish Water and Northern Ireland Water.

The Hydrological Summary and other NHMP outputs may also refer to and/or map soil moisture data for the UK. These data are provided by the Meteorological Office Rainfall and Evaporation Calculation System (MORECS). MORECS provides estimates of monthly soil moisture deficit in the form of averages over $40 \times 40 \mathrm{~km}$ grid squares over Great Britain and Northern Ireland. The monthly time series of data extends back to 1961.

Rainfall data are provided by the Met Office. To allow better spatial differentiation the rainfall data for Britain are presented for the regional divisions of the precursor organisations of the EA, NRW and SEPA. The areal rainfall figures have been produced by the Met Office National Climate Information Centre (NCIC), and are based on 5 km resolution gridded data from rain gauges. The majority of the full rain gauge network across the UK is operated by the EA, NRW, SEPA and Northern Ireland Water; supplementary rain gauges are operated by the Met Office. The Met Office NCIC monthly rainfall series extend back to 1910 and form the official source of UK areal
rainfall statistics which have been adopted by the NHMP. The gridding technique used is described in Perry MC and Hollis DM (2005) available at http://www.metoffice.gov.uk/ climate/uk/about/methods

Long-term averages are based on the period 1971-2000 and are derived from the monthly areal series.

The regional figures for the current month in the hydrological summaries are based on a limited rain gauge network so these (and the associated return periods) should be regarded as a guide only.

The monthly rainfall figures are provided by the Met Office NCIC and are Crown Copyright and may not be passed on to, or published by, any unauthorised person or organisation.

For further details on rainfall or MORECS data, please contact the Met Office:

[^0]:    Important note: Figures in the above table may be quoted provided their source is acknowledged (see page 12). Where appropriate, specific mention must be made of the uncertainties associated with the return period estimates. The RP estimates are based on data provided by the Met Office and reflect climatic variability since 1910; they also assume a stable climate. The quoted RPs relate to the specific timespans only; for the same timespans, but beginning in any month the RPs would be substantially shorter. The timespans featured do not purport to represent the critical periods for any particular water resource management zone. For hydrological or water resources assessments of drought severity, river flows and/or groundwater levels normally provide a better guide than return periods based on regional rainfall totals. Note that precipitation totals in winter months may be underestimated due to snowfall undercatch. All monthly rainfall totals from January 2016 (inclusive) are provisional.

[^1]:    ( ) figures in parentheses relate to gross storage

[^2]:    + excludes Lough Neagh
