33 **Bronze Age subsistence strategies in the southeastern Carpathian Bend area, Romania:**
34 **results from stable isotope analyses**

35

36 *Ülle Agurauja, Mihai Constantinescu, Angela Lamb, Clive Bonsall*

37

38 **Abstract**

39 Here we report the results of stable carbon and nitrogen isotope analyses of human and faunal
40 remains from two Bronze Age (Monteoru culture) sites near Buzău in Romania, in the eastern
41 foothills of the Carpathian Mountains. The results for 54 humans from Sărata Monteoru and
42 10 from Cărlomănești indicate diets that were dominated by C₃ terrestrial resources,
43 consistent with the archaeofaunal inventories from the sites and archaeobotanical data from
44 the wider region. Statistically significant differences in the average $\delta^{15}\text{N}$ values of the two
45 skeletal populations hint at a change in economic practices between early and late phases of
46 the Monteoru culture. Consumer diets at the two sites were quantified using multiple mixing
47 models generated with the Bayesian statistical program FRUITS (Food Reconstruction Using
48 Isotopic Transferred Signals). The model outputs suggest the inhabitants of the later
49 settlement, Sărata Monteoru, were less dependent on animal-derived products and relied
50 more on cereals and legumes for energy and protein, compared to their predecessors at
51 Cărlomănești. Based on changes in the faunal record we speculate that dairying may also
52 have increased in importance between the early and later phases of the Monteoru culture.

53

54 *Key words:* Bronze Age, Carpathian Bend, stable isotopes, subsistence, palaeodiets

55

56 **1. Introduction**

57 Along the eastern flank of the Carpathian Mountains, in present-day Romania, is a zone of
58 rolling hills and valleys known as the Sub-Carpathians. During the Bronze Age, this
59 region was inhabited by sedentary farmers of the Monteoru culture. The presence of
60 foreign goods among their archaeological remains hints at a society with trade contacts
61 extending as far as the Baltic and the Aegean (Motzoi-Chicideanu, 1995), yet relatively
62 little is known of the daily life of these people, including their dietary habits.

63 Palaeodiet studies using stable isotope data have been undertaken in Southeastern Europe
64 since the 1980s (Murray and Schoeninger, 1988), with particularly detailed research on
65 Mesolithic and Early Neolithic populations living along the Lower Danube in the ‘Iron
66 Gates’ (e.g. Bonsall et al., 1997, 2004; Cook et al., 2001; Borić et al., 2004; Nehlich et al.,
67 2010). For later periods, while there have been studies of Bronze and Iron Age
68 communities along the Adriatic and the Aegean coasts (e.g. Triantaphyllou et al., 2008;
69 Petroutsa and Manolis, 2010; Vika, 2011; Lightfoot et al., 2012, 2015), these periods in
70 the northern Balkans have been comparatively neglected.

71 Bronze Age economies in southeast Europe can be very broadly characterized by an
72 increase in cultivation intensity and crop diversity (including the spread of millet, a C₄
73 plant) (see Harding, 2000; Motuzaitė-Matuzevičiute et al., 2013; Stika and Heiss, 2013)
74 and a shift from caprine to cattle husbandry (Becker, 1999, 2000; Bartosiewicz, 2013).
75 The current study aims to investigate whether similar trends can be observed in the Sub-
76 Carpathian isotopic record.

77 In this paper, we present new stable isotope data for archaeological human and animal
78 remains from two Monteoru culture sites – Sărata Monteoru and Cărlomănești – to assess
79 the dietary practices of these Bronze Age communities and to provide quantitative
80 estimates of plant vs animal foods in Monteoru diet.
81

82 2. Archaeological background

83 The Monteoru culture is one of the richest Bronze Age cultures in Southeast Europe, and
84 one of the most thoroughly researched (Nestor, 1933; Vulpe, 1995; Motzoi-Chicideanu,
85 2011). The two sites included in our study, although only 12km apart, represent different
86 phases in the evolution of the Monteoru culture (**Figure 1**).
87

88
89 **Figure 1.** Map of Romania showing the area of the Monteoru culture and the locations of
90 Sărata Monteoru and Cărlomănești ('Location map of Romania' by Wikimedia Commons
91 user Dr Brains used under GNU Free Documentation Licence 1.2, modified by Ü.
92 Aguraiuja)

93
94 The type site, Sărata Monteoru, is a multi-layer, fortified, hilltop settlement spanning the
95 period from the Early Bronze Age to the end of the Middle Bronze Age, and has several
96 associated cemeteries – three on lower slopes of the same hill, and one on an adjacent
97 hillslope. Only the largest cemetery (no. 4) has been adequately published (Maximilian,
98 1962; Bârzu, 1989). Pottery typology and ¹⁴C dating (four unpublished radiocarbon dates
99 obtained by Mihai Constantinescu) place this cemetery in the middle of the second
100 millennium BC, ca. 1750–1500 cal BC. Although more than half the graves documented
101 in cemetery no. 4 have no grave goods, there are numerous 'rich' graves containing
102 objects made of valuable or exotic materials, such as bronze, gold, glass paste and amber
103 (Bârzu, 1989).

104 The site of Cârломănești has a similar environmental setting to Sărata Monteoru,
105 comprising a hilltop settlement (*The Citadel*) with a cemetery located on an adjacent hill,
106 the La Arman plateau. Only one radiocarbon date is available for the settlement, which
107 falls around 1600 cal BC (Motzoi-Chicideanu et al., 2012b), whereas 14 skeletons from
108 the cemetery were radiocarbon dated between ca. 2280–1800 cal BC (Motzoi-Chicideanu
109 and Chicideanu-Șandor, 2015). However, a significant part of the cemetery remains
110 unexcavated, and may contain burials from the later period, as suggested by the discovery
111 of a grave with Late Monteoru ceramics c. 300m from the excavated area. Thus, it is likely
112 that the cemetery and the settlement are contemporaneous (Constantinescu, personal
113 observation). The range of funerary goods recovered at Cârломănești is similar to that
114 found at Sărata Monteoru cemetery no. 4, although there are some differences in burial
115 customs and grave constructions – for example, at Cârломănești there were numerous
116 collective graves and secondary burials, and many graves had stone structures such as
117 stone-filled pits covered with small stone mounds, cists, or catacombs, often attributed to
118 eastern influence (Motzoi-Chicideanu, 2011; Motzoi-Chicideanu et al., 2012a).

119 Zooarchaeological evidence from Monteoru culture sites points to a focus on cattle and
120 caprine husbandry, supplemented by occasional hunting (Becker, 1999, 2000). Cultivation
121 of several varieties of cereals and pulses is evidenced by the presence in archaeobotanical
122 assemblages of emmer, einkorn, spelt, bread and durum wheat, barley, rye and gold-of-
123 pleasure, and pea and bitter vetch (Cârциumar, 1983, 1996). Although millet (the only
124 regularly grown C₄ plant in prehistoric Europe) has not been reported from Monteoru
125 culture sites, direct dating of millet grains indicates that it was cultivated in some areas of
126 Southeast Europe as early as the Middle Bronze Age, c. 1600 cal BC (Motuzaitė-
127 Matuzeviciute et al., 2013).

128 Aquatic resources would have been available in rivers and streams of the surrounding
129 landscape, although Sărata Monteoru and Cârломănești are some distance (10 and 2.8 km,
130 respectively) from the only large river in the region, the Buzău River. While fish and
131 shellfish may have been consumed on occasion, their remains were not found among the
132 faunal material from the sites, suggesting they are unlikely to have been more than a very
133 minor component of the diet.

134

135 3. Stable isotope analysis for dietary reconstruction

136 Stable isotopes of carbon and nitrogen, analysed from bone collagen, are commonly used
137 in archaeological research to estimate the proportion of marine vs terrestrial, or plant vs
138 animal resources at both the individual and population level. Carbon isotope ratios ($\delta^{13}\text{C}$)
139 can be used to distinguish between marine and terrestrial sources of carbon, but also
140 between diets based on either C₃ or C₄ plants. Humans living on C₃ plants or their
141 consumers have bone collagen $\delta^{13}\text{C}$ values around -20‰, while those relying mainly on
142 C₄ resources exhibit much higher values around -10‰; elevated $\delta^{13}\text{C}$ values also result
143 from regular consumption of marine foods (Schoeninger and DeNiro, 1984; Ambrose
144 and DeNiro, 1986; Sealy, 2001). Fish inhabiting freshwater rivers and lakes exhibit
145 widely varying C-isotope signatures. The $\delta^{13}\text{C}$ of fish bones from Mesolithic and Early
146 Neolithic sites in the Iron Gates of the Danube, for example, was found to range between
147 -26.3‰ and -15.7‰ (Bonsall et al., 1997), while Fuller et al. (2012) reported bone
148 collagen $\delta^{13}\text{C}$ values for freshwater and anadromous fish from historical period sites in
149 Belgium of between -28.2‰ and -14.1‰.

150 Nitrogen isotope ratios ($\delta^{15}\text{N}$) primarily reflect the trophic level of the organism – with
151 every step up the food chain there occurs an enrichment of ca. 3-6‰ in ^{15}N between the

152 food source and its consumer (Bocherens and Drucker, 2003; Hedges and Reynard,
153 2007). This results in plants having the lowest and top carnivores the highest $\delta^{15}\text{N}$
154 values. The longest food chains and thus the highest $\delta^{15}\text{N}$ values are seen in aquatic (both
155 freshwater and marine) ecosystems (Schoeninger and DeNiro, 1984).

156 While $\delta^{15}\text{N}$ in animal tissues varies in a relatively predictable manner, a broad range of
157 biogeochemical processes can influence the N isotopic composition of plants and soils at
158 the base of the food chain. Perhaps the most important of these for agricultural societies
159 is the effect of animal-derived fertilizers on plant $\delta^{15}\text{N}$ ratios (see Szpak [2014] for a
160 review). While elevated (up to 5–6‰) crop $\delta^{15}\text{N}$ values have been reported for charred
161 plant remains from prehistoric European contexts (e.g. Fraser et al., 2011, 2013; Bogaard
162 et al., 2013; Vaiglova et al., 2014; Bogaard, 2015), the extent to which manuring affects
163 plant $\delta^{15}\text{N}$ values seems to be highly variable, depending on the type and amount of the
164 fertilizer and the duration of the application, with more extensive and long-term
165 manuring practices resulting in more positive values. On occasions where high-intensity
166 manuring has affected plant $\delta^{15}\text{N}$ values, misinterpretation of human stable isotope data
167 can result in the overrepresentation of animal protein in human diets, as herbivores
168 consuming (unmanured) forage may be indistinguishable from manured crops based on
169 their collagen $\delta^{15}\text{N}$ values alone.
170

171 **4. Materials and methods**

172 Fifty-four individuals from Sărata Monteoru cemetery no. 4 and 10 individuals from
173 Cârломănești – La Arman were selected for stable $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ analysis. A rib bone was
174 sampled from most individuals, although other skeletal elements were used if a rib was not
175 available. Samples were selected to include both sexes, various age groups, and different
176 ‘social groups’ (based on the presence and amount of grave goods). Additionally, animal
177 bones recovered from graves in cemetery no. 4 (n=17) and from the Monteoru period
178 settlement at Cârломănești (n=39) were sampled to provide a regional terrestrial baseline
179 of faunal isotope values. Animal bones from Sărata Monteoru are believed to relate to
180 burial activities (e.g. grave goods or remains of feasting), although they were not
181 documented during the original excavations. Faunal samples from Cârломănești lack a
182 direct connection with the human burials, as they were recovered from the settlement site
183 near the cemetery, but they are assumed to be representative of the type of animal protein
184 consumed by the local inhabitants.

185 Approximately 1g of bone was cut from each of the human and animal bones selected for
186 analysis, using a Dremel multitool fitted with a diamond cutting wheel. Collagen for stable
187 isotope analysis was extracted at the University of Edinburgh Bone Chemistry Laboratory.
188 Bone samples were first cleaned of adhering sediment and 1-2mm removed from exposed
189 surfaces using a sterile scalpel blade, followed by ultrasonication in ultrapure (MilliQ™)
190 water. After drying, the cleaned samples were weighed and then subjected to standard
191 acid/base/acid (ABA) pre-treatment at room temperature, comprising demineralization in
192 1M HCl, followed by 0.2M NaOH wash for 20 minutes to remove humic acids, and a final
193 1M HCl wash for 1 hour to remove any secondary carbonates that may have formed
194 during NaOH treatment – after each step, the samples were rinsed three times with
195 ultrapure water. The residue was gelatinized in a pH 3 solution at 80°C for approximately
196 20 hours. The resulting solution was filtered, evaporated until about 10ml remained,
197 freeze-dried, then weighed to determine percent yield.

198 Collagen samples were measured for $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ at the NERC Isotope Geosciences
199 Laboratory facility at Keyworth (UK), using a Continuous Flow-Elemental Analysis-
200 Isotope Ratio Mass Spectrometry (CF-EA-IRMS) consisting of an elemental analyser
201 (Flash/EA) coupled to a ThermoFinniganDelta^{Plus} XL isotope ratio mass spectrometer via
202 a ConFlo III interface. Collagen carbon and nitrogen isotope ratios are reported in per mil
203 (‰) relative to VPDB and AIR standards, respectively. $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ ratios were
204 calibrated using an in-house reference material M1360p (powdered gelatine from British
205 Drug Houses) with expected delta values of -20.32‰ (calibrated against CH7, IAEA) and
206 +8.12‰ (calibrated against N-1 and N-2, IAEA) for C and N, respectively. Analyses were
207 run in duplicate and the average 1-sigma standard deviation of the duplicates was
208 $\delta^{13}\text{C}=\pm 0.06\text{‰}$ and $\delta^{15}\text{N}=\pm 0.05\text{‰}$. The 1-sigma reproducibility for mass spectrometry
209 controls for these analyses was better than $\pm 0.14\text{‰}$ for $\delta^{13}\text{C}$ and $\pm 0.06\text{‰}$ for $\delta^{15}\text{N}$.
210

211 **5. Results**

212 The stable isotope data for the human and animal bone samples analysed are presented in
213 **Tables 1 & 2** and **Figures 2 & 3**.

214 Collagen yields for all samples were >1% and atomic C:N ratios between 3.2 and 3.4,
215 indicative of well-preserved collagen (van Klinken, 1999). Most samples also had
216 elemental concentrations within the range of $\geq 30\%$ for %C and $\geq 10\%$ for %N defined by
217 van Klinken (1999).

218 In three cases, %C and %N were below that range, but still within the accepted lower
219 limits of 13 for %C and 5 for %N (Ambrose, 1990). Since these samples also had C:N
220 ratios indicative of well-preserved collagen, and the values themselves do not seem
221 abnormal, they were not discarded.

240

241 **6. Discussion**

242 6.1. Sărata Monteoru

243 The average isotope values for all Sărata Monteoru individuals (n=54) were $-19.5 \pm 0.3\%$
 244 for $\delta^{13}\text{C}$ and $+8.8 \pm 1.0\%$ for $\delta^{15}\text{N}$ (**Table 1, Figure 3**). This is consistent with a terrestrial
 245 diet based on C_3 plants and plant consumers.

246 While the $\delta^{13}\text{C}$ range is relatively small (-20.1% to -18.8%), there is significant variation
 247 in $\delta^{15}\text{N}$ values (from $+5.8\%$ to $+11.1\%$). The highest and lowest $\delta^{15}\text{N}$ values generally
 248 belong to juveniles (here defined as between 0-15 years), although excluding the juveniles
 249 has little effect on mean $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values ($-19.5\% \pm 0.2\%$ and $+8.7\% \pm 0.8\%$,
 250 respectively).

251 Burial no. 40 (17–19-year-old female) is an outlier, with an exceptionally low $\delta^{15}\text{N}$ value
 252 of $+5.8\%$. The quality indicators for this sample are within accepted limits and, if not due
 253 to contamination or measurement error, this result would imply an almost exclusively
 254 plant-based diet. For modern vegans, hair keratin $\delta^{15}\text{N}$ values as low as $+5.5\%$ have been
 255 reported (Petzke et al., 2005; see also O’Connell and Hedges, 1999), but since human hair
 256 has been shown to be on average 0.86% lower in $\delta^{15}\text{N}$ than bone collagen from the same
 257 individual (O’Connell et al., 2001), none of the modern vegans would likely have had
 258 bone collagen values as low as that seen in the Sărata Monteoru outlier.

259 Among adolescents (here defined as from the age 15 onwards) and adults, 17 females and
 260 12 males could be identified. The average values for adult females ($-19.6\% \pm 0.3\%$;
 261 $+8.6\% \pm 1.0\%$) and males ($-19.4\% \pm 0.2\%$; $+8.9\% \pm 0.6\%$) were similar; removing the
 262 outlier (burial 40) mentioned above from the female group would result in almost identical
 263 mean $\delta^{15}\text{N}$ values for both groups (mean female $\delta^{15}\text{N}$ without the outlier is $+8.8\% \pm 0.6$).
 264 With or without the outlier, there were no statistically significant differences in $\delta^{13}\text{C}$ or
 265 $\delta^{15}\text{N}$ related to the sex of the individual (Mann-Whitney U test, $p > 0.05$ for both variables).

266 $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values also showed no statistically significant differences between
 267 juveniles, adolescents and adults (Kruskal-Wallis H test, $p > 0.05$ for both variables).
 268 However, the difference would be statistically significant if juveniles were separated into
 269 two groups: those under 4 years old (n=9, mean values of -19.3% and $+9.7\%$); and those
 270 over 4 years old (n=8, mean values of -19.8% and $+7.9\%$) (Kruskal-Wallis H test,
 271 $H=7.392$, d.f.=2, $p=0.025$ for $\delta^{13}\text{C}$, and $H=10.739$, d.f.=2, $p=0.005$ for $\delta^{15}\text{N}$; post hoc
 272 analyses showed the difference to lie between the younger and older juvenile groups for
 273 both $\delta^{13}\text{C}$ [$p=0.022$] and $\delta^{15}\text{N}$ [$p=0.003$]).

274 The higher $\delta^{15}\text{N}$ (and $\delta^{13}\text{C}$) values of infants reflect the well-documented breastfeeding
 275 effect (see Fuller et al., 2006). Here, infants display $\delta^{15}\text{N}$ values up to 2.5% higher (and up
 276 to 1.2% for $\delta^{13}\text{C}$) compared to the female mean, with elevated values starting to drop from
 277 age 3 years onwards.

278 The lower $\delta^{15}\text{N}$ values for older juveniles have been documented in other studies (e.g.
 279 Richards et al., 2002; Nitsch et al., 2011), and are sometimes attributed to the childhood
 280 diet containing lower trophic-level foods (e.g. cereals) as weaning foods (Tsutaya and
 281 Yoneda, 2013). An alternative explanation for the observed lower $\delta^{15}\text{N}$ values of older
 282 children involves the influence of positive nitrogen balance during growth (Katzenberg
 283 and Lovell, 1999; Fuller et al., 2004). However, Waters-Rist and Katzenberg (2010)

284 concluded that the effects of growth (i.e. positive nitrogen balance) are too minor to
285 significantly affect $\delta^{15}\text{N}$ values in juvenile bone collagen.

286 The quality and quantity of grave goods has traditionally been associated with social
287 status, with a more impressive funerary inventory taken as an indicator for wealth, power
288 and/or prestige. However, differentiating burials based on the number of grave goods is
289 subjective, as the quantity of grave goods and their value to the deceased or to the people
290 who buried them may have been unrelated either to wealth or the status of the individual.
291 In the current project, a distinction was made between those buried without grave goods,
292 those buried with ‘few’ grave goods (consisting of only ceramic vessels or a single
293 artefact), and those buried with a ‘rich’ inventory (consisting of two or more artefacts, at
294 least one of which was made from a material other than ceramics). The isotope data show
295 no statistically significant differences between any of these groups ($p>0.05$ for all
296 variables). The lack of a correlation between isotope ratios and the number of grave goods
297 implies that those members of the community buried without grave goods did not consume
298 significantly (i.e. isotopically) different diets from those buried with funerary objects.
299

300 6.2. Cârломănești

301 The average isotope values for all Cârломănești individuals ($n=10$) were -19.3‰ ($\pm 0.2\text{‰}$)
302 for $\delta^{13}\text{C}$ and $+9.6\text{‰}$ ($\pm 0.4\text{‰}$) for $\delta^{15}\text{N}$ (**Table 1, Figure 3**). Cârломănești human values
303 display a more restricted range compared to Sărata Monteoru, but this may be an effect of
304 the small sample size. Given the small data set, no statistical analyses were conducted;
305 however, it is worth noting that the $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values of the one adult male individual
306 fall entirely within the range of the four females from the same site. The Cârломănești
307 sample set did not include any infants (i.e. those under 4 years of age), but mean values for
308 older juveniles ($n=4$) and adults/adolescents ($n=6$) follow a similar trend to Sărata
309 Monteoru where adult $\delta^{15}\text{N}$ values are slightly higher than those of younger individuals.
310 All individuals analysed from Cârломănești were buried with grave goods, but there are no
311 clear differences in the isotope values of burials according to the number or type of items
312 included in the grave.
313

314 6.3. Faunal isotope values

315 Cârломănești faunal samples ($n=38$) showed a much wider range of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values
316 (-13.5‰ to -22.1‰ for $\delta^{13}\text{C}$, $+2.8\text{‰}$ to $+9.9\text{‰}$ for $\delta^{15}\text{N}$) compared to Sărata Monteoru
317 ($n=17$) (-18.9‰ to -20.7‰ for $\delta^{13}\text{C}$, $+5.4\text{‰}$ to $+9.8\text{‰}$ for $\delta^{15}\text{N}$), however, the two ranges
318 overlap and the mean values for livestock (cattle, caprines, pigs) from the two sites are not
319 statistically different (Cârломănești -19.6‰ [$\pm 1.7\text{‰}$], $+6.3\text{‰}$ [$\pm 0.9\text{‰}$]; Sărata Monteoru
320 -19.7‰ [$\pm 0.5\text{‰}$], $+6.7\text{‰}$ [$\pm 1.1\text{‰}$], for $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$, respectively) (**Table 2**). The greater
321 range for Cârломănești may be influenced by the larger sample size, or by the
322 archaeological material originating from various Monteoru-era layers of the settlement site
323 (and thus potentially representing a longer period).

324 There is considerable variation in faunal $\delta^{15}\text{N}$ values for both sites, and in $\delta^{13}\text{C}$ values for
325 Cârломănești. Some of the higher $\delta^{15}\text{N}$ values may originate from suckling animals (which
326 would thus display the nursing effect), or from selective consumption of manured plants
327 with elevated $\delta^{15}\text{N}$ values. The lowest $\delta^{15}\text{N}$ values were seen in wild herbivores but also in
328 (some) horses. $\delta^{13}\text{C}$ values for herbivores were generally consistent with diets based on C_3
329 plants. However, there are several outliers, all from Cârломănești: two caprines (sheep or
330 goat) have $\delta^{13}\text{C}$ values of -16.4‰ and -17.1‰ , which suggest a significant contribution to

331 diet from C₄ resources; while one pig has the highest $\delta^{13}\text{C}$ value (-13.5‰) of any sample
332 analysed. Since none of the humans nor any of the other ungulates display such high $\delta^{13}\text{C}$
333 values, it seems likely these animals were distinct from the ‘regular’ Monteoru herds,
334 suggesting there was movement of livestock over large distances through long-distance
335 herding, trade activities, or gift exchange; alternatively, the outliers could represent
336 wild/feral forms. A fourth outlier is another caprine with a $\delta^{13}\text{C}$ value of -22.1‰, >1‰
337 lower than measured in any other faunal sample from either site (including the two wild
338 herbivores with $\delta^{13}\text{C}$ values as low as -20.8‰).

339 Dogs were kept already by the Mesolithic fishing communities of the Iron Gates
340 (Bökönyi, 1972), and their importance in Monteoru society is reinforced by their constant
341 presence in archaeozoological assemblages from the Carpathians from the Eneolithic
342 onwards (Becker, 1999, 2000). Dog isotope values from both sites are similar to those of
343 humans (on average $-19.4 \pm 0.3\text{‰}$ [$\delta^{13}\text{C}$]; $+9.2 \pm 0.7\text{‰}$ [$\delta^{15}\text{N}$]), while their $\delta^{15}\text{N}$ values are
344 significantly higher than those of the (domestic and wild) herbivores analysed (Kruskal–
345 Wallis H test, $H=26.626$, d.f.=5, $p<0.0001$). These data are consistent with the dogs
346 having been fed (or allowed to scavenge) on human food waste that included a significant
347 amount of animal protein, and this is supported by numerous finds from Monteoru
348 settlements of animal bones (e.g. of cattle, pig, caprines) with canid gnaw marks (Becker,
349 1999, 2000), including three bones from Cârломănești (two caprines and one suid)
350 sampled for the current study (Agurauja, personal observation). While Becker (2000)
351 reported cut-marks on canid bones from Monteoru culture sites (including Sărata
352 Monteoru), the similarity of dog-human $\delta^{15}\text{N}$ ratios suggests that dog meat was not
353 consumed in significant quantities by humans here.
354

355 6.4. Inter-site differences

356 The mean isotope values for all humans from Sărata Monteoru ($-19.5\text{‰} \pm 0.3\text{‰}$ for $\delta^{13}\text{C}$
357 and $+8.8\text{‰} \pm 1.0\text{‰}$ for $\delta^{15}\text{N}$) and Cârломănești ($-19.3\text{‰} \pm 0.2\text{‰}$ and $+9.6\text{‰} \pm 0.4\text{‰}$) are
358 statistically significantly different for $\delta^{15}\text{N}$ (Mann-Whitney U test, $U=447$, $p=0.001$) but
359 not for $\delta^{13}\text{C}$ (Mann-Whitney U test, $U=370$, $p=0.063$), and this is also true when juvenile
360 individuals are excluded. If the youngest individuals (i.e. under 4-year-olds) are excluded,
361 then the differences are statistically significant for both $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ ($p<0.02$ for both
362 variables).

363 The Sărata Monteoru population is characterised by slightly lower average $\delta^{13}\text{C}$ and
364 noticeably lower $\delta^{15}\text{N}$ values compared to Cârломănești. These differences are unlikely to
365 be due to variations in local baseline isotope values, since faunal isotope values from the
366 two sites are similar. **Figure 3** displays the average values for humans (excluding
367 juveniles) from both sites with 1SD error bars, plotted against mean values for animals
368 from both sites (excluding the above-mentioned outliers in the faunal data set with unusual
369 $\delta^{13}\text{C}$ values).

370 At Sărata Monteoru, cattle and caprines – the principal livestock species, according to
371 their dominance in Monteoru archaeozoological assemblages (see Becker, 1999, 2000) –
372 have average $\delta^{15}\text{N}$ values 2.3‰ lower than humans, while for Cârломănești $\Delta^{15}\text{N}$ between
373 livestock and human averages is 3.6‰. Given livestock $\delta^{15}\text{N}$ values are similar between
374 the two sites, the higher human $\delta^{15}\text{N}$ values for Cârломănești can be explained in several
375 ways:

376 A. The inhabitants of the earlier site, Cârломănești, regularly consumed more animal
377 protein than the later, Sărata Monteoru, community;

- 378 B. The two populations had diets with similar amounts of animal protein, but the
 379 inhabitants of Sărata Monteoru consumed much more animal protein in the form of
 380 dairy products, which tend to be slightly depleted in both ^{13}C and ^{15}N compared to
 381 meat from the same animal (Nardoto et al., 2006; Huelsemann et al., 2013);
- 382 C. Both communities consumed similar proportions of plant and animal protein but
 383 the Cârломănești community grew plant food for human consumption with the aid
 384 of intensive manuring;
- 385 D. Both communities consumed similar amounts of animal protein, but the inhabitants
 386 of Cârломănești had a strong preference for meat from very young (suckling)
 387 animals or pork from pigs that were stall fed on food waste containing animal
 388 protein and/or protein from crops grown under intensive manuring;
- 389 E. Since Cârломănești was much closer to the Buzău River, its inhabitants had greater
 390 access to freshwater fish.

391 Hypotheses D and E lack support from the archaeofaunal data, and so are considered
 392 unlikely. Moreover, if pigs were reared on food waste, this is more likely to have occurred
 393 at Sărata Monteoru given the comparatively high $\delta^{15}\text{N}$ values of the pigs from that site
 394 (**Table 2**).
 395

396 6.5. Quantitative diet reconstruction

397 To further explore intra-site differences, we used the Bayesian statistical program FRUITS
 398 (Food Reconstruction Using Transferred Isotopic Signals, beta 2.1.1) (Fernandes et al.,
 399 2014) to model the diets of the skeletal populations from Sărata Monteoru and
 400 Cârломănești.

401 Using FRUITS, it is possible to consider more than two food groups, as well as factors
 402 such as differences in protein content between food groups. The program calculates
 403 probability estimates of the proportions of different foods in diet, given the consumer's
 404 stable isotope values and those of the different food groups.

405 We assumed that Bronze Age diets at Cârломănești and Sărata Monteoru comprised three
 406 food groups: animals, cereals and legumes. The population means (excluding juveniles)
 407 were used as the consumer values. For animals, the site average for the most commonly
 408 utilized domesticated species (cattle and caprines, excluding outliers) was used. In the
 409 absence of local plant baseline data, published isotope values of Neolithic crops from
 410 Germany, Hungary and Bulgaria (Fraser et al., 2011, 2013; Bogaard et al., 2013; Bogaard,
 411 2015) were used as proxies. Based on these published data, cereal values were set as -24‰
 412 and +2‰, and legume values as -24‰ and 0‰, for $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$, respectively.

413 Two different scenarios were modelled – *unmanured plants* with 'typical' $\delta^{15}\text{N}$ values for
 414 cereals and legumes (see above), and *manured plants* with more elevated values observed
 415 in the same plants grown under intensive manuring – to allow for the possibility that
 416 regular manuring of crops intended for human consumption may have influenced the
 417 human $\delta^{15}\text{N}$ data. The values for manured plants were set as +5‰ for cereals and +2‰ for
 418 legumes, based on data from Bogaard et al. (2013), Fraser et al. (2011, 2013), and Bogaard
 419 (2015).
 420

421 **Table 3.** Base values applied in the FRUITS model: consumer value (site average), the
 422 different food groups, and their fractions for each dietary proxy (^{13}C , ^{15}N) along with their

423
424

associated uncertainty (‰) (set as 1-sigma error for consumers and animals, and ± 0.5 for values that were not directly measured)

425

426 The isotopic composition of food group macronutrients was calculated based on
427 previously reported offsets between macronutrient and collagen isotope values,
428 summarized in Fernandes et al. (2014, 2015). For terrestrial animal meat, the offsets are
429 $\Delta^{13}\text{C}_{\text{protein-collagen}} = -2\text{‰}$, $\Delta^{13}\text{C}_{\text{energy-collagen}} = -8\text{‰}$, $\Delta^{15}\text{N}_{\text{protein-collagen}} = +2\text{‰}$; for cereal crops
430 and legumes $\Delta^{13}\text{C}_{\text{protein-collagen}} = -2\text{‰}$, $\Delta^{13}\text{C}_{\text{energy-collagen}} = +0.5\text{‰}$. The diet-to-collagen
431 isotopic offsets for $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ were set as $4.8 \pm 0.5\text{‰}$ (Fernandes et al., 2012) and
432 $5 \pm 1\text{‰}$ (Hedges and Reynard, 2007; O'Connell et al., 2012), respectively. The full list of
433 parameter values used for the two sites and for both scenarios is given in **Table 3**.

434 **Table 4** provides an overview of the estimates generated by FRUITS for the four different
435 scenarios. Scenarios 1 (Sărata Monteoru) and 3 (Cârlomănești) take into account the
436 potential manuring effect on both cereals and legumes, reflected in higher plant $\delta^{15}\text{N}$
437 values; scenarios 2 (Sărata Monteoru) and 4 (Cârlomănești) consider unmanured values
438 for plants. The estimates represent calorie contributions for each food group, the calorie
439 contribution from each food fraction, and the calorie contribution of each food group
440 toward an isotopic proxy (either ^{13}C or ^{15}N). The estimates for ^{13}C and ^{15}N differ due to
441 the former including a routed carbon contribution from energy (i.e. carbohydrates and
442 lipids). The margin of error on individual estimates ranges between 12% and 25%, which
443 demands caution when interpreting the results. Combining the data for Proxy (Food) (%)
444 would reduce the errors to between 10% and 15% (see **Table 4**).

445

446 **Table 4.** Estimates generated by FRUITS (%) with 1-sigma error for Sărata Monteoru
447 and Cârlomănești populations and for both dietary scenarios. Energy includes both lipids

448 *and carbohydrates. The estimates represent calorie contributions for each food group*
 449 *(Food [%]), the calorie contribution from each food fraction (Fraction [%]), and the*
 450 *calorie contribution of each food group toward an isotopic proxy (¹³C, ¹⁵N, and the*
 451 *weighted mean of the two) (Proxy [%])*

452

453 Despite the large error range, there are apparent differences in the model estimates for
 454 both sites depending on whether values for manured or unmanured plants were used.
 455 Based on high crop $\delta^{15}\text{N}$ values, some authors (e.g. Bogaard et al., 2013; Fraser et al.,
 456 2013; Vaiglova et al., 2014; Bogaard, 2015) have proposed that manuring was widely
 457 practised among Central and Southeast European farmers since the Neolithic. However,
 458 Monteoru settlements were often located on fertile black earth (chernozem) soils which
 459 tend to maintain their fertility naturally without frequent manuring. While this does not
 460 exclude the possibility that low-intensity manuring occurred incidentally, i.e. by animals
 461 grazing near the farmlands or on fallow fields, without direct data from associated plant
 462 remains it is impossible to determine the real effect (if any) of manuring on Monteoru
 463 $\delta^{15}\text{N}$ values.

464 As suggested above from the $\Delta^{15}\text{N}_{\text{human-herbivore}}$ values for each site, the model predicts
 465 greater reliance on animal products at Cârlomănești. Irrespective of whether manured or
 466 unmanured scenarios are compared, the contribution of animal-based foods to total calorie
 467 intake, total dietary protein and total dietary energy on average are 10–14% greater for
 468 Cârlomănești compared to Sărata Monteoru. When lower plant $\delta^{15}\text{N}$ values, characteristic
 469 of unmanured crops, are used the model predicts on average ca. 15% greater importance in
 470 both sites of animal-based protein compared to legume-derived protein.

471 For both sites, the model predicts that plant foods accounted for most of the calories
 472 consumed, and in most scenarios plant protein also accounted for more than half of total
 473 protein intake. Estimates for the cereal food group showed the least variability, suggesting

474 similar contributions for both sites, irrespective of the presence or absence of a manuring
475 effect on plant $\delta^{15}\text{N}$ values. Manured values led to greater estimated contributions from
476 legumes to total calorie intake, with scenario 1 (Sărata Monteoru, manured plants)
477 displaying the highest contribution of legumes to both total calorie intake (ca. 46%) and to
478 dietary protein (ca. 54%). Even at Cârломănești, for which the model predicts a lower
479 contribution from legumes, they are still estimated to account for at least a quarter of total
480 calorie intake, and to contribute significantly to dietary protein.

481 Based on archaeobotanical evidence from Southeast Europe from the Neolithic onwards,
482 the protein-rich legumes were grown on a consistent basis throughout the region, although
483 they are usually reported in smaller numbers compared to remains of wheat and barley
484 (e.g. Gyulai, 1993; Cârциumar, 1996; Monah, 2007; Reed, 2013). According to Bonsall et
485 al. (2007), ethnohistorical sources suggest that a typical peasant farming society in
486 Southeast Europe commonly received most of their sustenance from cultivated plants such
487 as cereals, legumes and fruits, with only a modest contribution from dairy products (meat
488 was regarded as luxury). This is in accordance with the model's predictions for the two
489 Monteoru sites.

490 While the modelled estimates have large associated uncertainties, the results nevertheless
491 suggest differences in the way dietary resources were utilized between the two sites, and
492 possibly, also between the Early and Late Monteoru periods. The most likely
493 interpretation of the available data involves a modest decrease at later-period Sărata
494 Monteoru in dependence on animal-derived products and a greater reliance on plant
495 carbohydrates for energy, with legumes increasing in importance as a source of dietary
496 protein over animal protein. This trend seems consistent when comparing scenarios 1 and
497 3 (both sites, manured plants), 2 and 4 (both sites, unmanured plants), 1 and 4 (Sărata
498 Monteoru manured, Cârломănești unmanured), but does not hold in comparisons between
499 scenarios 2 and 3 (Sărata Monteoru unmanured, Cârломănești manured).

500 Given the similarities of the palaeoecological and archaeological material recovered from
501 each site, a significant change in economic activities is an unlikely explanation for the
502 observed differences. While no clear trend can be discerned between Early and Middle
503 Bronze Age faunal assemblages from the Monteoru culture area, available
504 archaeozoological evidence for the Eneolithic and Bronze Age Carpathians does indicate a
505 shift from caprine to cattle husbandry during the Bronze Age, with cattle becoming the
506 dominant species by the Late Bronze Age (Becker, 1999, 2000). The rise in the
507 importance of cattle husbandry during the Carpathian Bronze Age may have increased the
508 amount of milk available for dairy products; alternatively, a rise in the popularity of, or
509 developments, in dairying may have led to the preferential keeping of cows. The maturity
510 of cattle in several middle Danube sites during the second millennium BC has also been
511 taken to imply an important role for dairy cows (Barker, 1989). Additionally, as animals
512 kept for dairying would be slaughtered less often than those kept for meat, it would
513 presumably reduce the amount of (cattle) meat consumed – and the calories obtained from
514 animal products. It is thus possible that a change in dietary practices between the Early
515 and Late Monteoru periods as represented by the two sites included in this study may have
516 involved a shift from a more meat-based economy to a more dairy- and plant-based
517 economy.

518

519 **7. Conclusions**

520 The results from stable carbon and nitrogen isotope analyses for Monteoru culture humans
521 and fauna reflect a dietary regime that was dominated by C₃ terrestrial resources. The
522 Sărata Monteoru population is characterised by significantly lower average $\delta^{15}\text{N}$ and
523 slightly lower average $\delta^{13}\text{C}$ compared to Cărlomănești. Since faunal isotope values from
524 the two sites are similar (excluding the outliers with relatively high $\delta^{13}\text{C}$ values, which
525 could reflect movement of livestock over large distances), these differences are unlikely to
526 be due to variation in local baseline isotope values. Estimates generated by FRUITS
527 suggest that while plant foods – both cereals and legumes – were an important source of
528 calories and dietary protein throughout the Monteoru period, inhabitants of the earlier
529 settlement, Cărlomănești, were more dependent on animal-derived products compared to
530 the population sampled from Sărata Monteoru.

531 The difference in the average $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values of the two skeletal populations
532 suggests a change in economic activities between the early and late phases of the
533 Monteoru culture, possibly characterised by a shift from a more meat-based economy to a
534 more dairy- and plant-based economy. However, as this is only the first major stable
535 isotope study conducted on osteological material from the Romanian Sub-Carpathians,
536 more data are needed to determine whether the observed shift is a true temporal trend or
537 merely reflects site-specific dietary preferences.

538 Interpretation of the stable isotope data are constrained by the lack of associated plant
539 remains, which are necessary to clarify the issue of the effects of manuring on human and
540 faunal isotope ratios. There is also a need for paired ^{14}C and stable isotope measurements
541 to more fully explore changes in dietary practices throughout the Carpathian Bronze Age.
542 Further work is underway to explore other aspects of Monteoru culture subsistence,
543 including sulphur isotope analysis (to investigate mobility of livestock) and incremental
544 analysis of teeth dentine (to elucidate weaning practices).
