12 **Abstract**

13 The world-class Cuiabá gold deposit of the Archaean Rio das Velhas greenstone belt in Brazil is hosted in banded iron

14 formation containing carbonaceous matter and carbonate, within the reclined, isoclinal Cuiabá fold. Mineralised quartz veins

15 are hosted in andesite in the stratigraphic footwall of the banded iron ores and form some of the more recently discovered ore

16 bodies. Fluid inclusion data of the quartz-vein associated 'Veio de Quartzo' ore body are obtained from five quartz types

17 (Qz1, Qz2, Qz3, Qz5) in gold mineralised V1 shear veins and V2 extensional veins, barren V3 extensional vein arrays and

18 V4 breccia-style veins, all developed during the Archaean D1 event. Three fluid types are distinguished: (i) aqueous fluids of

19 low salinity (1.8–3.8 wt% NaCl equiv.), homogenisation (into liquid) at 220 to 230°C; (ii) aqueous fluids of moderate salinity

20 (5.3–12.7 wt% NaCl equiv.) and homogenisation at 250 to 290°C; and (iii) aqueous-carbonic fluids of moderate salinity (6.0–

21 15.1 wt% NaCl equiv.), with 30–91 mol% CO_2, 8–41 mol% CH_4 and up 28 mol% N_2 and decrepitation (into vapour) at 280

22 to 310°C. Based on an independent pressure estimate a pressure correction was applied to aqueous fluid inclusions, resulting

23 in minimum trapping temperatures at 360°C for V1 veins, 330°C for V2 veins, 300°C for V3 veins and 270°C for the late-

24 stage V4 veins. Ion chromatography analyses reveal a Br/Cl ratio of $0.7x10^{-3}$ in Qz1-V1, from 1.4 to $1.5x10^{-3}$ in Qz2-V2, 0.3

25 to $0.4x10^{-3}$ in Qz3-V3 and 0.7 to $0.9x10^{-3}$in Qz5-V4 veins. Zinc, Pb and Cu are relatively enriched, with ~ 100 to 1,000 ppm

26 in aqueous and aqueous-carbonic fluid inclusion assemblages in all vein and quartz types, which is similar to other orogenic

27 gold deposits hosted in the Rio das Velhas greenstone belt. The fluid inclusion data are consistent with a model invoking a

28 metamorphic origin for the mineralising fluid. A two-step model of hydrothermal fluid flow and gold enrichment is suggested

29 to have developed during the Archaean D1 event, with an early, aqueous-carbonic fluid pulse of relatively high temperature

30 (from V1 up to V3) and an evolved, aqueous-carbonic fluid pulse of lower temperature (V4, breccias-style veins).

Introduction

32 Orogenic lode-gold deposits are hosted in metamorphic terranes that typically contain rocks of lower to upper greenschist

33 facies metamorphic grade (Groves et al. 1998). Textural and structural relationships are commonly well preserved allowing

34 important constraints on the deposit formation. Fluid inclusion studies, summarised by Ridley and Diamond (2000) and

35 Goldfarb and Groves (2015), suggest that ore formation occurred from aqueous-carbonic, CO_2/CH_4 fluids of low to moderate

36 salinities. The source of gold is still debated (Goldfarb and Groves, 2015). As pointed out by Gaboury (2013, 2019), the record

37 of aqueous-carbonic and hydrocarbon gases in fluids from orogenic gold deposits confirms that organic matter-rich

38 sedimentary rocks, containing possible gold-bearing pyrite, could be in part the source for gold in many world-class gold

39 deposits. However, sedimentary rocks only form a small proportion of most Archaean greenstone belts (Goldfarb and Groves

40 2015). Compositional microanalysis of fluid inclusions using laser ablation-inductively coupled plasma-mass spectroscopy

41 (LA-ICP-MS) has the potential to provide new information on the origin and evolution of crustal fluids (Marsala et al. 2013;

42 Rauchenstein-Martinek et al. 2014, 2016; Morales et al. 2016; Wagner et al. 2016; Fusswinkel et al. 2017).

43 The Quadrilátero Ferrífero (QF) region is one of Brazil's most important gold provinces (Lobato et al. 2001a, b) and hosts

44 a range of Archaean to Cenozoic gold deposits. The most productive deposits are hosted in banded iron formations (BIF) of

45 the Archaean Rio das Velhas greenstone belt (Lobato et al. 2014) (Fig. 1). Some of the largest gold deposits, including Morro

46 Velho, Cuiabá, São Bento and Raposos, are located in the basal unit of this greenstone belt, referred to as the Nova Lima

47 Group (Ladeira 1991; Vieira 1991; Lobato et al. 1998). The Cuiabá deposit, situated ~40 km northeast of Belo Horizonte

48 (Fig. 1), is presently the major gold producer in the QF. The total of the Cuiabá mine's mineral resources, considering

49 measured, indicated and inferred resources is 19.7 million tonnes grading 10.58 g/t Au (AngloGold Ashanti 2018).

50 Previous fluid inclusion studies of orogenic gold deposits hosted in the Rio das Velhas greenstone belt included those by

51 Xavier et al. (2000), Lobato et al. (2001a, b, c), Ribeiro et al. (2015) and Morales et al. (2016). The study by Xavier et al.

52 (2000) showed that the mineralising fluids were dominantly aqueous with a low salinity (3.0–6.0 wt% NaCl equiv.) and

53 variable concentrations of CO_2 (0–11.4 mol%), CH_4 (1.5–10.2 mol%), subordinate N_2 (0–0.7 mol%) and traces of H_2S and/or

54 HS. The work of Lobato et al. (2001a, b, c) noted the occurrence of aqueous and aqueous-carbonic fluid inclusions with

55 salinities ranging from 1.4 to 12.8 wt% NaCl equiv. and inconsistent volatile compositions of CO_2 (3.5–90.5mol%), CH_4

56 (64.0–94.5 mol%), N_2 (1.5–21.5 mol%) and H_2S (~1.3 mol%).

57   This contribution reports on a study conducted to determine the chemistry of the hydrothermal fluids that formed the quartz

58 vein-associated, andesite-hosted ore bodies at the Cuiabá gold deposit. In contrast to previous studies, fluid inclusion

59 assemblages (FIAs) were studied to provide meaningful fluid inclusion data, as well as new geochemical data obtained by

60 LA-ICP-MS. Based on the vein and quartz classification, new fluid inclusion data and spectroscopic investigations provide

61 critical information on the mineralising processes at this world-class deposit.

Geology of the Quadrilátero Ferrífero including the Rio das Velhas greenstone belt

63 The Quadrilátero Ferrífero (QF) is located in the southern São Francisco Craton (Dorr 1969) and encompasses Archaean

64 gneissic trondhjemite-tonalite-granodiorite (TTG) terranes, Archaean granite-greenstone belts of the Rio das Velhas

65 Supergroup and Proterozoic sedimentary units of the Minas and Espinhaço Supergroups (Dorr 1969; Toledo 1997; Noce

66 2013). Banded migmatite gneisses make up the largest proportion of the crystalline basement of the QF. They comprise four

67 main lithostructural domains, consisting of 3.2 Ga granitoid gneisses and minor sedimentary rocks, which are intruded by

68 2.8–2.7 Ga old tonalites, andesites, granites, pegmatites and Proterozoic mafic dikes (Noce et al. 2005; Moreira et al. 2016).

69   The Rio das Velhas Supergroup contains the Archaean Rio das Velhas greenstone belt (3.0–2.7 Ga; Machado et al. 1989)

70 which comprises the Nova Lima Group at the base and the overlying Maquiné Group (Fig. 1). The greenstone belt rocks are

71 regionally metamorphosed to lower greenschist facies. The lower portion of the Nova Lima Group is composed of lower

72 komatiitic to tholeiitic volcanic rocks interlayered with clastic and exhalative chemical sedimentary rocks (Vieira 1988). The

73 middle mafic and felsic volcanic rocks are interlayered with carbonaceous sedimentary rocks and BIF with felsic

74 volcaniclastic rocks on the top. Clastic sedimentary rocks interlayered with mafic and felsic volcaniclastic rocks form the

75 upper portion of the Nova Lima Group (Fig. 1). Radiometric ages (U-Pb-SHRIMP) of detrital zircons yield a minimum age

76 of 2.74 Ga for the volcaniclastic rocks (Schrank and Machado 1996; Lobato et al. 2001a).

77   The Paleoproterozoic Minas Supergroup (2.6-2.1 Ga; Babinski et al. 1991) represents a continental margin sequence and

78 comprises clastic and chemical sedimentary rocks. More recently, however, Cabral et al. (2012) dated zircons (U-Pb LA-ICP-

79 MS) from a volcanic layer within the Minas Supergroup iron formation and proposed a 2.65 Ga Neoarchaean age for the

80 deposition of these rocks.

Geology of the Cuiabá gold deposit

The Cuiabá deposit is an Archaean (U-Pb SHRIMP age of 2672±14 Ma on monazite; Lobato et al. 2007) gold deposit, presently exploited in an underground mine. The host rock succession was first defined by Vial (1980) and consists of volcanic, volcaniclastic and sedimentary rocks that form part of the Nova Lima Group (Ladeira 1991).

At Cuiabá, the lowermost stratigraphic unit is characterised by alternating units of chloritised, mafic volcanic and pelitic rocks, which are carbonate and sericite altered (Figs. 2c, ESM-1), as well as interbedded lenses of carbonaceous pelite. The volcanic and pelitic rocks are overlain by the Algoma-type Cuiabá BIF. The Cuiabá BIF consists of rhythmic alternation of dark, white and ocher-coloured, millimeter- to centimeter-thick bands, rich in carbonaceous matter and fine-grained quartz and carbonate (ESM-1). Its lower portion is typically banded and rich in Fe-carbonate and carbonaceous matter. The upper portion, separated by a 15-cm-thick mafic volcanic unit, is a highly deformed ferruginous chert also containing carbonaceous matter. Overlying these chemical sedimentary rocks, is an upper mafic volcanic unit that displays a similar mineralogical composition as the lower, chloritised mafic volcanic rocks. Metamorphosed andesite at Cuiabá consists of albite, epidote, zoisite (clinozoisite), quartz, actinolite, carbonate and chlorite (Vieira 1991). The rocks are characterised by a light green colour and a fine grain size and are massive or foliated (ESM-1). The absence of hornblende indicates that peak metamorphic conditions did not exceed the greenschist-amphibolite facies transition (Spear 1995). This mineral assemblage is characteristic of metamorphic temperatures of 350 to 450°C and is stable over a large pressure range of up to 4 kbars (Spear 1995). The stratigraphic column is completed by a ~1000-m-thick section of volcaniclastic rocks (Vieira 1991; Lobato et al. 1998; Xavier et al. 2000).

Structural setting

The rocks at the Cuiabá deposit underwent at least three deformation events (Ribeiro-Rodrigues et al. 2007). The first two, D1 and D2, developed under ductile to ductile-brittle conditions of SE-NW-directed compressive stress, with tectonic transport from SE to NW. The brittle-ductile D3 structures formed due to E-W-oriented compressive stress (Ribeiro-Rodrigues et al. 2007). All lithological units are overprinted by a pervasive axial planar foliation that is locally mylonitic (S_m= 135/45). They show a prominent mineral stretching lineation (LS = 126/22–35) indicated by the preferred orientation of elongated sericite, carbonates and sulphide minerals. Late, northwest-verging, sigmoidal thrust faults reactivated pre-existing structures and caused folding, boudinage and rotation of the host rocks of the Cuiabá deposit (Vitorino 2017).

The Cuiabá fold is an anticline with the rock succession inverted along the north limb (Fig. 2a). The N116° fold axis plunges from 35° in the upper portion to 12° below level 18. The plunge direction controls the geometry of the mineralised ore bodies. Studies by Vial (1980), Toledo (1997), Ribeiro-Rodrigues (1998) and Ribeiro-Rodrigues et al. (2007) considered the Cuiabá

110 fold as a tubular structure, plunging southeast at 30º. Recently published data for the nearby Lamego gold deposit (Fig. 1)

111 suggests that its fold geometry, which is comparable to that of the Cuiabá fold, represents a reclined, isoclinal, cylindrical and

112 rootless fold (Martins et al. 2016).

Gold mineralisation

114 Gold mineralisation at Cuiabá is contained in six main BIF-hosted ore bodies (> 4 g/t Au) referred to as Balancão, Canta Galo,

115 Fonte Grande, Fonte Grande Sul (FGS), Serrotinho and Galinheiro (Fig. 2a). These ore bodies represent sulphide-rich

116 segments of the Cuiabá BIF grading laterally into non-economic or barren iron formation. Quartz vein-hosted ore bodies are

117 named Veio de Quartzo (VQZ), Galinheiro Footwall (GAL FW), Serrotinho Footwall (SER FW) and FGS Footwall (FGS

118 FW) (Fig. 2). The three main mineralisation styles are: (i) stratabound-replacement with locally massive ores, commonly in

119 BIF, (ii) disseminated in volcanic and sedimentary rocks, related to hydrothermal alteration in shear zones and (iii) quartz-

120 carbonate-sulphide veins related to shear-zones in volcanic and sedimentary rocks (Ribeiro-Rodrigues et al. 2007).

121 Decreases in gold grade from over 60 g/t Au to values below the detection limit of the fire assay in sulphide-poor portions

122 always indicate transitions from sulphide-rich to -poor BIF. Gold, ranging in size from 10 to 80 µm, is intergrown with pyrite,

123 pyrrhotite and arsenopyrite. It occurs in fractures or along grain boundaries of pyrite and arsenopyrite. Pyrite is the most

124 common sulphide and accounts for >90% by volume of all sulphides. Most of the pyrite forms porous grains that may be

125 zoned, displaying As-rich centres.

126 The Fonte Grande Sul ore body is located in the SE closure of the Cuiabá fold (Fig. 2a). It is the largest and highest grade

127 ore body in the deposit. Resources are calculated at 4.91 million tonnes grading 13.87 g/t Au, with additional reserves of 0.8

128 million tonnes grading 8.11 g/t Au (AngloGold Ashanti 2018). The thickness of the ore body varies between 4 and 6 m. The

129 mineralised BIF is intensely sulphidised (ESM-1), folded and disrupted, containing generally disseminated and massive ores

130 that lack banding.

131 The recently discovered VQZ ore body (Fig. 2a) has significant gold grades associated with andesite-hosted quartz-rich

132 shear veins and is located between levels 9 and 17 in the southeastern part of the Cuiabá fold hinge (Fig. 2b). Mineralisation

133 is predominantly controlled by a strike-slip, oblique shear zone, with native gold hosted in quartz-rich shear veins and

134 disseminated sulphide minerals in hydrothermally altered country rocks. The Au grade reaches up to ~500 g/t due to the

135 presence of free coarse gold (Vitorino 2017).

136 Hydrothermal alteration studies at Cuiabá were carried out by Vieira (1988, 1991), Ribeiro-Rodrigues (1998) and Lobato

137 et al. (1998, 2001a,b). These authors showed that the carbonaceous pelites are only locally altered by sulphide-quartz-

138 carbonate veinlets and that the Cuiabá-BIF is strongly sulphidised. Mafic volcanic rocks are overprinted by pervasive

139 alteration, where distal alteration comprises an assemblage of chlorite, carbonate±sericite and sulphide minerals, intermediate

140 alteration is characterised by an assemblage of carbonates, chlorite, quartz, plagioclase and sulphide minerals and the proximal

141 alteration is composed of quartz, sericite, sulphide minerals and free gold.

Materials and methods

143 Quartz vein samples for fluid inclusion analyses were taken from drill cores CBABSD007 and CBABSD009 intersecting the

144 VQZ ore body at Level 17 (Fig. 2c) and underground exposures of shear and extensional veins of the andesite-hosted VQZ

145 ore body at Level 15 of the Cuiabá mine (Figs. 2b; 3g-i).

146 The fluid inclusion study was carried out on vein quartz of the S_m (mylonitic foliation)-related mineralised quartz-sulphide

147 and barren quartz veins. Nine doubly polished thick sections were prepared and petrographically mapped in transmitted light.

148 Four of them were chosen for microthermometry. Measurements were conducted using a Linkam THMSG 600 heating and

149 freezing stage with a T95 temperature programmer at the Laboratory of Metallogeny, Institute of Geoscience, at the Federal

150 University of Minas Gerais, Brazil. The stage was calibrated with synthetic inclusions. All measurements were collected by

151 predetermined temperature profiles that include a sequence of step-by-step continuous heating or cooling rates. Heating

152 sequences have been performed slowly to prevent decrepitation. Calculated salinity (wt% NaCl equiv.), bulk composition of

153 all FIAs, as well as pressure and temperature values to construct isochores, were obtained using the MacFlinCor program

154 (Brown and Hagemann 1995). Eutectic temperatures of aqueous FIAs range between –45 and –35°C, indicating a mix of

155 different salts (Borisenko 1977; Goldstein and Reynolds 1994). For measured FIAs that show final ice-melting temperatures

156 above the eutectic for H_2O-NaCl (<–21.2°C), the equation of state by Bodnar and Vityk (1994) was used for the H_2O-NaCl-

157 (KCl) system. In the case of clathrate melting temperatures, (Tm_{Clath}) the equation of Jacobs and Kerrick (1981) for the H_2O-

158 CO_2-CH_4-NaCl was applied due to the presence of CO_2 and/or CH_4. Measurement of homogenisation temperatures of the

159 CO_2 phase (Th_{CO2}) is limited to inclusions larger than 10 μm. The $Th_{TOT(L-V)}$ were obtained from Qz2 of V2 extensional veins

160 and V3 extensional vein arrays, as well as Qz5 from V4 late-stage veins. Measurements on various aqueous-carbonic FIAs

161 with probably higher proportions of volatile phases (CH_4, H_2S, N_2) did not allow salinity calculations with Tm_{Clath} above 10

162 to 16°C.

163 Raman spectroscopy investigations were carried out at the Institute of Engineering at the Federal University of Minas

164 Gerais, Brazil. Raman spectra were obtained using a Jobin Yvon/Horiba LABRAM-HR 800 spectrograph equipped with a

165 He-Ne laser (632.8 nm) and linked to a N_2 liquid cooled CCD (charge coupled device) detector. The excitation and collection

166 of the scattered light was achieved using an Olympus BHX microscope focused on single fluid inclusions at high

167 magnification (50x or 100x objectives). Acquisition times varied between 10 and 30 s depending on the background

168 fluorescence of the fluid inclusions. Laser-Raman analyses were applied to several types of aqueous and aqueous-carbonic

169 FIAs in different quartz types. Complex gas mixtures of CO_2, CH_4, N_2 and a limited set of solutes have been detected within

170 each non-aqueous phase at ambient P-T conditions. Data processing of all Raman spectra was conducted using the software

171 Labspec 5. Semiquantitative determination of gas species (CO_2, CH_4 and N_2) and their relative abundances (in mol%) used

172 the method of Burke (2001). Wavelength-dependent relative Raman scattering cross sections (σ532 nm) for each gas species

173 were determined by interpolation from Burke (2001). The instrumental efficiency for all components was set to 0.92 in all

174 calculations based on Garofalo et al. (2014). Uncertainties in calculated mole fractions of species present in the carbonic phase

175 of the inclusions are within 20% relative.

176 Ion chromatography was performed on quartz samples of the andesite-hosted quartz shear and extensional veins at the

177 School of Earth and Environment, University of Leeds. Quartz samples were reduced to a grain size of 0.5–1 mm and

178 contaminant minerals removed by picking under a binocular microscope. Quartz types of V1 and V2 veins were separated.

179 However, mixing of several fluid inclusion populations contained in the quartz cannot be ruled out. Samples and duplicates

180 were cleaned three times with 18.2 MΩ Milli-Q water. Dry samples were crushed to a fine powder in an agate pestle and

181 mortar and 7 mL of water was added to redissolve the contents of the fluid inclusions. The solution was filtered through a

182 0.2 μm nylon filter to remove any particles. Cl^-, Br^- and SO_4^{2-} were determined by using ion chromatography. The leachates

183 were analysed for cations such as Na^+, K^+ and Li^+ by atomic emission spectroscopy. As the amount of fluid inclusions leached

184 is unknown, molar ratios are used.

185 Laser ablation ICP-MS analyses on FIAs trapped in quartz of shear and extensional veins were conducted at the School of

186 Earth and Environment, University of Leeds. The calibration was performed using the standard NIST 610. Fluid inclusion

187 and standard measurements were conducted by using the GeoLas Q Plus excimer laser (ArF, 193 nm, Microlas, Göttingen,

188 Germany). The optical system permits visual observation of the ablation process through a built-in LED source and CCD

189 camera. The material liberated during the ablation is carried by He, purging the ablation cell, into the Agilent 7500 quadrupole

190 mass spectrometer. An octopole reaction cell was used for analyses of ^{40}Ca and ^{56}Fe. A detailed description of the LA-ICP-

191 MS procedure is given in Allan et al. (2005). Elements including Na, K, Ca, Mg, Mn, Fe, Cu, Zn, Sr, Ag, Ba, Pb, As and Au

192 were analysed. Arsenic and Au were measured separately for each vein type to avoid signal interference. Data reduction was

193 conducted with the Matlab based SILLS program (Guillong et al. 2008). LA-ICP-MS intensity ratios for fluid inclusions were

194 normalised to Na and converted to concentration ratios by external calibration against NIST 610 standard reference material.

195 For the determination of Na concentration, the average salinity of each FIA was used. The analytical error of LA-ICP-MS

196 measurements and data processed required the use of average salinity values for each analysed FIA. Detection limits vary

197 according to inclusion volume, but for most elements were between 1 and 10 ppm.

The Cuiabá quartz veins

199 In Cuiabá, the quartz veins hosted in andesite can be classified as (i) fault-fill, (ii) extensional (oblique-extensional) and (iii)

200 breccia veins according to the criteria of Passchier (2001) and Robert and Poulsen (2001) (Table 1; adapted from Vitorino,

201 2017). Vein types are also subdivided based on their crosscutting relationships, relative chronology and mineralogical

202 composition into V1 to V4 vein systems (Table 1). According to Vitorino (2017) all vein types are related to Archaean D1

203 brittle-ductile shear zones and located in the mineralised zones VQZ, SER FW and FGS FW. Shear veins are most common

204 in the studied VQZ ore body.

205 The VQZ ore body (Fig. 2a, b) is made-up of four vein types (Table 1) with the following vein classification based on the

206 structural model proposed by Vitorino (2017). Both shear and extensional veins show a similar paragenesis, but differ in terms

207 of relative proportions of quartz types, carbonate, sulphide and accessory minerals (Table 1).

Vein type classification

209 Shear veins (V1), the most abundant in the VQZ ore body, were emplaced during D1 shearing and are parallel to slightly

210 oblique to the main mylonitic S_m foliation (Fig. 3a). They extend ~30 to 50 m along strike and are up to 30 m in thickness.

211 Their long axis coincides with the mineral lineation Lmin1. They mainly consist of anhedral, smoky quartz (Qz1; Fig. 3g),

212 minor granoblastic, milky quartz (Qz2), ankerite, sericite, chlorite and albite and contain fragments of host rocks. Accessory

213 minerals are pyrite, pyrrhotite, chalcopyrite, sphalerite and native gold. Wall rock fragments show ductile deformation, are

214 typically sericite-altered and sulphide-rich and may contain significant gold.

215 The extensional V2 veins are hosted in andesite and controlled by the compositional banding S_b, occurring either at a high

216 angle or subparallel with respect to the mylonitic S_m foliation (Fig. 3b). They represent the most abundant vein type in the

217 center of the Cuiabá fold and may occur tens to hundreds of meters from the D1 shear zone. Commonly continuous along

218 strike, they can extend for 200 m and range between a few centimetres up to 2 m in thickness. There are mutual cross-cutting

219 relationships between V1 and V2 types. The V2 veins are mainly composed of Qz2, ankerite, sericite, chlorite and minor

220 pyrite, pyrrhotite and chalcopyrite (Fig. 3h).

221　　The V3 extensional vein arrays are at high angle with the mylonitic S_m foliation, having an average thickness from 5 to 30

222　　cm. The V3 extensional vein arrays are mainly composed of euhedral quartz (Qz3) (Fig. 3f inset) and are immersed within

223　　the V1 shear veins (Fig. 3c, f; Table 1).

224　　The V4 extensional veins (hereafter designated as V4 late-stage veins) show massive and tabular vein geometries (Fig. 3d,

225　　e). Wall rock fragments are located in the inner part of the veins and impose a brecciated structure. These are controlled by

226　　flanking structures (flanking folds and flanking shear bands, cf. Passchier 2001) and barren. They mainly consist of Qz5,

227　　carbonate (ankerite, calcite) and locally pyrrhotite and pyrite (Fig. 3d, i, Table 1); these sulphides are present as centimetre to

228　　up to 10 cm sized agglomerates and locally as well formed grains.

229　　**Quartz type classification**

230　　Four main quartz types (Qz1, Qz2, Qz3 and Qz5) are discriminated mainly based on morphological characteristics. The Qz1

231　　is typically smoky, anhedral, medium- to coarse-grained, with strong wavy extinction; it is rich in fluid inclusions. The grain

232　　boundaries of Qz1 are interlobate (Fig. 4c, d). The polygonal granoblastic, fine- to medium-grained Qz2 developed at the

233　　expense of Qz1 (Fig. 4a, c, d), mainly along crystal boundaries. The proportion of fluid inclusions is relatively low compared

234　　to Qz1. Vitreous Qz3 is polygonal and shows well defined limits of coarse- to very coarse-grained transparent euhedral

235　　crystals that are locally transformed to granoblastic Qz4 (Fig. 4e). The Qz3 and Qz4 contain a moderate amount of fluid

236　　inclusions. Qz5 shows similar morphological features to Qz1.

237　　**Fluid inclusion data of the VQZ ore body**

238　　**Fluid inclusion classification and description**

239　　The results of detailed petrography constraining the size, shape and L/V phase ratio of fluid inclusions, their occurrence as

240　　groups, trails or individual inclusions are provided in Table 2. Emphasis was placed on the identification of FIAs, which are

241　　defined as the most finely discriminated fluid inclusion trapping event that can be identified based on petrography (Goldstein

242　　and Reynolds 1994). In total, 20 distinct FIAs are observed and numbered (1–20, subscript are indicated by subscript

243　　characters). The FIAs in internal trails and three-dimensional groups, with respect to individual quartz grains, are

244　　pseudosecondary in nature, whereas trails crosscutting quartz grain boundaries are determined as secondary in origin (Sterner

245　　and Bodnar 1984; Wilkinson 2001). Secondary FIAs and FIAs that appear randomly and cannot be constrained with respect

246　　to their relative timing of trapping, defined as indeterminate, are not further considered in this investigation.

9

247   This study focuses on primary and pseudosecondary FIAs, which are present in all vein and quartz types except Qz4 (Fig.

248   5, Table 2). Primary and pseudosecondary FIAs are defined by: (i) aqueous-carbonic fluid inclusions, irregular to ovoid-

249   shaped, 5–10 µm, locally up to 15 µm in size and contain about 10 vol.% vapour; and (ii) aqueous fluid inclusions, regular to

250   ovoid shaped, about 5–10 µm in size with about 5–10 vol.% vapour.

Microthermometry results

V1 shear veins

253   Aqueous fluid inclusions in Qz1 show eutectic temperatures (T_e) between –43 to –39°C; Tm_{ice} between (i) –9.5 and –5.1°C

254   and (ii) –3.5 and –1.1°C. The $T_{DECREP\ (L)}$ ranges between 220 and 250°C (Fig. 6c, Table 3). Salinity values range from (i) 1.8

255   to 5.6 wt% NaCl equiv. and (ii) 8.1 up to 13.4 wt% NaCl equiv. (Fig. 6a).

256   Aqueous-carbonic fluid inclusions display Tm_{CO_2} between –61.7 and –58.1°C; Tm_{Clath} between (i) 1.2 and 3.6°C and (ii)

257   6.1 and 6.6°C; Th_{CO_2} between 25.1 and 30.4°C and $T_{DECREP(V)}$ between 280 and 310°C (Fig. 6c, Table 4). Aqueous-carbonic

258   fluid inclusions indicate salinities ranging from 7.2 to 12.7 wt% NaCl equiv. (Fig. 6c). The bulk density varies between 1.02

259   and 1.05 g/cm^3.

V2 extensional veins

261   Aqueous fluid inclusions in Qz2 display T_e between (i) –44 and –42°C and (ii) –45 to –35°C; Tm_{ice} between –5.2 and –3.3°C;

262   $Th_{TOT(L)}$ from 260 to 290°C (FIA 11$_D$) and $T_{DECREP(L)}$ at 325°C (Fig. 6b). Salinity values range from 5.0 to 8.5 wt% NaCl

263   equiv. (Fig. 6a, Table 3). Aqueous-carbonic fluid inclusions in Qz1 show Tm_{Clath} between 15.1 and 16.8°C and $T_{DECREP(L)}$

264   from 215 to 275°C (Table 4).

V3 extensional vein arrays

266   Aqueous fluid inclusions in (i) Qz1 and (ii) Qz2 show T_e between (i) –43 to –39°C and (ii) –39 to –35°C; Tm_{ice} between (i)–

267   8.9 and –7.0°C and (ii) –5.5 and –3.0°C and $T_{DECREP(L)}$ between 190 and 230°C. Average salinities of aqueous fluid inclusions

268   in Qz1 range from 10.5 to 12.7 wt% NaCl equiv. Homogenisation into vapor of FIAs in Qz2 is observed at 220°C and 230°C

269   (Fig. 6b). Average salinities of aqueous fluid inclusions in Qz2 range from 4.9 to 8.5 wt% NaCl equiv. (Fig. 6a). Aqueous

270   fluid inclusions in Qz3 show T_e between –35 to –30°C; Tm_{ice} between –6.3 and –1.8°C; $T_{DECREP(L)}$ between 210 and 270°C

271   with outliers up to 350°C (Table 3). Salinity values for range between 3.0 and 9.5 wt% NaCl equiv. (Fig. 6a, Table 3).

272   Aqueous-carbonic fluid inclusions in Qz3 show Tm_{CO_2} from –61.0 to –57.2°C; Tm_{Clath} between 0.4 and 6.8°C and $T_{DECREP(V)}$

273   between 220° and 290°C (Fig. 6c, Table 4). Salinity values of fluid inclusions vary from 6.0 to 10.1, with outliers up to 15.1

274   wt% NaCl equiv. (Fig. 6a, Table 4). The bulk density of FIAs varies between 1.02 and 1.09 g/cm^3.

275   **V4 late-stage veins**

276   Aqueous fluid inclusions display T_e between –44 and –38°C, with Tm_{ice} ranges between –7.0 and –3.9°C. Homogenisation

277   temperatures (into L) vary from 175 to 195°C (Fig. 6b). Decrepitation temperatures (into L) are observed between (i) 210 and

278   220°C and (ii) 220 and 260°C (Table 3). Salinity values range between (i) 6.2 and 8.0 wt% and (ii) 8.9 and 10.5 wt% NaCl

279   equiv. (Fig. 6a, Table 3).

280   Aqueous-carbonic fluid inclusions in Qz5 show Tm_{CO_2} between –61.5 and –59.9°C and Tm_{Clath} between (i) 0.3 and 3.6 and

281   (ii) 6.1 and 8.1°C (Table 4). The Th_{CO_2} was not observed due to the small size of the fluid inclusions. The salinity ranges from

282   3.7 to 15.1 wt% NaCl equiv. in fluid inclusions in Qz5 (Fig. 6a, Table 4). The bulk density of aqueous-carbonic fluid inclusions

283   ranges from 1.01 up to 1.08 g/cm^3 (FIA 12_B).

284   **Raman spectroscopy**

285   The majority of non-aqueous phases of FIAs in all quartz and vein types are characterised by Raman bands of gaseous

286   components such as CO_2, CH_4 and N_2. Methane shows a constant and single symmetric stretching band at approximately 2909

287   cm^{-1} (± 5 cm^{-1}) (ESM-3). The presence of CO_2, located at 1281 cm^{-1} (± 3 cm^{-1}) and 1384 cm-1 (± 3 cm^{-1}), was detected in

288   aqueous-carbonic fluid inclusions trapped in Qz1-V1 shear veins (ESM-3). Nitrogen (at 2324 ± 2 cm^{-1}) and dissolved HS^- (at

289   2574 cm^{-1}) have been recorded only in low intensity in aqueous-carbonic fluid inclusions in Qz3-V3 extensional vein arrays

290   (ESM-3). Aqueous fluid inclusions in Qz2-V2 and Qz2-V3 extensional vein arrays show significant lower amounts of CH_4

291   and no CO_2. The Raman spectrum of molecular CO_2 shows two strong bands at 1281 cm^{-1} (± 3 cm^{-1}) and 1384 cm^{-1} (± 3 cm^{-1}

292   ^{1}) (ESM-3).

293   The calculations of the non-aqueous phase of individual fluid inclusions of FIA 8_{C+E}, in Qz1-V1 shear veins, resulted in 91.4

294   mol% CO_2 and 8.6 mol% CH_4, whereas the non-aqueous phase of individual fluid inclusions of FIA4_C in Qz3-V3 extensional

295   vein arrays are composed of 30.0 mol% CO_2, 41.0 mol% CH_4 and 28.0 mol% N_2. The FIAs 11_{A-E} in Qz2-V2 extensional veins

296   display CH_4 fluid inclusions only with count rates between 400 and 880.

297   **Trapping conditions**

298 No petrographic evidence for phase immiscibility (cf. Ramboz et al. 1982) has been observed in the samples analysed. Due to

299 the lack of independent pressure estimate and without observing any homogenisation temperature for aqueous-carbonic fluid

300 inclusions, the decrepitation temperatures are interpreted as minimum trapping temperatures (cf. Roedder 1984). In the case of

301 aqueous fluid inclusions, a temperature (pressure) correction can be applied using an independent pressure estimate, the Potter

302 (1977) equation of state and interactive graphs in the MacFlinCor program (Brown and Hagemann 1995). The independent

303 pressure estimate of 1.5 kbars is derived from the metamorphic mineral assemblage that characterises the host rocks in the

304 Cuiabá gold deposit (Vieira 1991; Lobato et al. 2001c). These pressures are interpreted to reflect the approximate pressure

305 conditions at the time of mineralisation, which are compatible with a mesozonal (1–2 kbars at 4–8 km paleodepth level

306 assuming lithostatic pressure conditions) crustal setting for Cuiabá (cf. Hagemann and Brown 1996; Hagemann and Cassidy

307 2000, Ridley and Diamond 2000).

308 Homogenisation and decrepitation as well as calculated trapping temperatures of FIAs are shown in Table 5 and Figure 6b/d.

309 A possible indication for phase immiscibility is provided by one aqueous, FIA 2_D, trapped in Qz2-V3 vein. In this assemblage,

310 vapour-rich fluid inclusions all homogenised into vapour at about 220°C (Table 3). The majority of the FIAs in Qz1-V1 shear

311 veins and Qz3-V3 extensional vein arrays decrepitated prior to homogenisation into vapour.

312 Based on the Th_{TRAP} of aqueous and minimum Th_{TRAP} of aqueous-carbonic FIAs, isochores were calculated for aqueous FIAs

313 11_{A-E} (5.8 wt% NaCl equiv.) and aqueous FIA 9 (8.5 wt% NaCl equiv.), both trapped in Qz2-V2 extensional vein and from

314 aqueous-carbonic FIA 8_E (7.2 wt% NaCl equiv.). Isochores were calculated based on the equation of state of Bodnar and Vityk

315 (1994) for aqueous FIAs and Jacobs and Kerrick (1981) for aqueous-carbonic FIAs. Using the intersection of the 'maximum'

316 isochores of aqueous FIAs 11_{A-E} and aqueous-carbonic FIA 8_E with the crystallisation temperature of 300–390°C for

317 arsenopyrites in the proximal alteration zone (Kresse 2018), an average pressure between 1.1 and 3.2 kbars is estimated (Fig.

318 6e).

319 **Ion chromatography**

320 The ion chromatography data for all vein types show that fluid inclusions are dominated by Na and K, with lesser amounts of

321 Li (Table 6). Chloride ion (Cl^-) and SO_4^{2-} are the major anions in quartz-hosted fluid inclusions. Significant SO_4 values may

322 be attributed to the presence of sulphides and their subsequent oxidation and/or leaching. Fluid inclusions of the V4 late-stage

323 veins display maximum chloride values of up to 32,600 ppb. Bromide values are variable, but the highest are in fluid inclusions

324 of the V2 extensional veins (Table 6).

Laser ablation ICP-MS

Analytical results for FIAs trapped in quartz from V1, V2, V3 and V4 veins show that Na^+, Ca^{2+}, K^+ and Mg^{2+} are the dominant cations and are discussed for each vein type below. Analyses of As and Au (Fig. 7) were conducted separately in aqueous FIAs trapped in Qz1-V1, Qz2-V2 and Qz5-V4 veins, because of possible interferences with other trace element signals (ESM-4). This data set is discussed separately below. Sodium and K were measured simultaneously. The average LA-ICP-MS concentration data for all FIAs analysed are provided in the ESM-5.

V1 shear veins

Quantitative LA-ICP-MS microanalysis of FIAs yielded one distinct population of data with a signature of Na>K>Ca>Mg (Fig. 8). The solutes of aqueous-carbonic fluid inclusions are elevated in Sr and Ba in comparison to aqueous inclusions (ESM-5). Base metal concentrations are in the order of 60–1,600 ppm (Fig. 8). The maximum Fe concentrations are in the range of 218 to 788 ppm. Manganese concentrations range from 33 to 61 ppm in aqueous fluid inclusions, whereas aqueous-carbonics show a large range from 34 to 111 ppm (ESM-5).

V2 extensional veins

Aqueous fluid inclusions in Qz2-V2 veins have lower K and Na and higher Mg and Ca concentrations in comparison to aqueous and aqueous-carbonic fluid inclusions in Qz1-V1 shear veins. For example, Sr and Ba concentrations are elevated in aqueous fluid inclusions in Qz2 compared to fluid inclusions in Qz1-V1, Qz3-V3 and Qz5-V4 veins (Fig. 8). Base metal concentrations range between 200 and 600 ppm in aqueous fluid inclusions (Fig. 9), with Zn being below detection limit.

V3 extensional vein arrays

Fluid inclusions in Qz3-V3 veins show the dominance of Na-K (Na>K>Ca>Mg). Alkali elements and base metals of fluid inclusions in Qz1 and Qz2 coincide with values of fluid inclusions in Qz1-V1 veins (Fig. 8; ESM-5). Strontium and Ba in aqueous fluid inclusions in Qz1 reach concentrations up to 456 and 327 ppm, respectively (ESM-5). Fluid inclusions trapped in Qz3 yield less Sr and Ba than fluid inclusions in Qz1-V3 veins (ESM-5).

V4 late-stage veins

348   Aqueous fluid inclusions trapped in Qz5-V4 late-stage veins are characterised by much higher Na concentrations compared

349   to aqueous and aqueous-carbonic fluid inclusions in Qz1-V1, Qz2-V2 and Qz3-V3 veins (Fig. 8). Strontium reaches values

350   up to 342 ppm and Ba up to 93 ppm in aqueous fluid inclusions (Table 8). Base metals display similar ranges compared to

351   the other vein types.

352   **Gold and arsenic concentration data**

353   Figure 7 shows the correlation between As and Au of fluid inclusions trapped in V1, V2 and V4 veins. Aqueous fluid

354   inclusions trapped in Qz1-V1 shear veins, characterised by a salinity range from of 8.1 to 13.4 wt% NaCl equiv., shows a

355   positive correlation of As and Au, yielding two populations. Population A is characterised by relatively low As (20–200 ppm)

356   and low Au (1–15 ppm) concentrations, whereas population B has higher As (up to 369 ppm) and Au concentrations (41 ppm)

357   (Fig. 7; ESM-4). Moderately saline fluid inclusions (4.9 to 8.0 wt% NaCl equiv.) trapped in Qz2-V2 veins show elevated As

358   and Au concentrations (Fig. 7). These FIAs have lower Na concentrations, but an elevated K signature (ESM-4). Laser ICP-

359   MS data of aqueous fluid inclusions trapped in Qz5 with a salinity range from 6.4 to 9.6 wt% NaCl equiv. plot at relatively

360   elevated As and Au concentrations coinciding with the population B of V1 veins (Fig. 7) and a maximum Au value of 56 ppm

361   (Fig. 7; ESM-4).

362   **Discussion**

363   **Microthermometry and Raman spectroscopy**

364   The CO_2-CH_4-rich FIAs in shear-related, andesite-hosted quartz veins of the VQZ ore body, Archaean Cuiabá gold deposit

365   (Fig. 2a), indicate three different fluid types: 1) aqueous of low salinity (1.8–3.8 wt% NaCl equiv.), 2) aqueous of moderate

366   salinity (5.3–12.7 wt% NaCl equiv.) and 3) aqueous-carbonic of low to moderate salinity (6.0–15.1 wt% NaCl equiv.) with

367   variable mol% CO_2 (30–91 mol%), CH_4 (8.6–41mol%), N_2 (maximum values of 28 mol%) and trace concentrations of HS^- in

368   the non-aqueous phase.

369   Many orogenic gold deposits hosted in metasedimentary rocks contain N_2 and/or CH_4 at concentrations similar to that of

370   CO_2 (Bodnar et al. 2014). Overall, fluid inclusion microthermometry and Raman data are comparable to those compiled for

371   metamorphic fluids by Ridley and Diamond (2000), Ribeiro et al. (2015) and Morales et al. (2016). Previous studies on Cuiabá

372   by Xavier et al. (2000) and Lobato et al. (2001a, b) showed low-salinity (3–6 wt% NaCl equiv.), H_2O-CH_4-CO_2 ($\pm$ N_2+HS)

ore-forming fluids. Methane-rich fluid inclusion types are abundant in quartz veins cross-cutting the organic carbon-bearing BIF of the Cuiabá deposit (Lobato et al. 2001c).

Ion chromatography

Three groups of ion chromatography results are depicted in Figure 9a, with the highest Cl/Br ratios (Table 6) corresponding to fluid inclusions in the Qz3-V3 extensional vein arrays (inset in Figure 9a). They all plot to the left of the seawater evaporation line, indicating that during water-rock interaction Na in the fluid was partly exchanged for other cations (Lüders et al. 2005). This Na loss is in agreement with the LA-ICP-MS data, which demonstrates average Na concentration in FIAs decreasing from V1 shear to V2 extensional veins and V3 extensional vein arrays (Fig. 8), with renewed Na increase in FIAs trapped in Qz5-V4 late-stage veins (Figs. 8, 9a). According to Lüders et al. (2005), Marsala et al. (2013) and Rauchenstein-Martinek et al. (2016), leaching of organic-rich sedimentary rocks increases Br and lowers the Cl/Br and Na/Br ratios, characterising data above the seawater evaporation line (as Qz2 of V2 veins; Fig. 9a). Given that in Cuiabá organic-bearing carbonaceous pelites (Fig. 2a) are associated with the Cuiabá BIF, and the Cuiabá BIF itself is containing carbonaceous matter, the low Cl/Br ratios (Table 6) may be interpreted similarly. An alternative for the low Cl/Br ratios is the mobilisation of Br during metamorphic devolatilisation of organic-rich sedimentary rocks (cf. Muramatsu and Wedepohl 1998).

Crush-leach and LA-ICP-MS studies by Leisen et al. (2012) and Fusswinkel et al. (2017) on euhedral fissure and cavity quartz samples from Alpine quartz veins and the Neoarchaean Pampalo orogenic gold deposit, respectively record lower molar Cl/Br ratios (9–150) than those of modern seawater. Low ratios are compatible with metamorphic fluids, whereby higher molar Cl/Br ratios are considered to be typical of magmatic-hydrothermal fluids (Fusswinkel et al. 2017) (500–1,600). In the case of Cuiabá, there is no indication of magmatic activity associated with gold mineralisation. One alternative to explain the moderate fluid salinity (15.1 wt% NaCl equiv.; Tables 3 and 4) and high Cl/Br ratios (Qz3, Fig. 9a inset) would be to invoke an evaporitic source.

For various orogenic gold deposits in Victoria, Australia, Fu et al. (2012) suggested that low-salinity, H_2O–CO_2 fluids, generated during transitional greenschist-amphibolite facies metamorphism of variably altered basalts, preserve their halogen signatures (Br/Cl ratio of $1.3\pm0.3\times10^{-3}$; Jambon et al. 1995). The Br/Cl ratios in Qz1-V1 shear and Qz5-V4 late-stage veins yield similar ranges (Table 6). The euhedral Qz3 has the comparably lowest Br/Cl ratios (Fig. 9b, Table 6). The Br/Cl ratios of fluid inclusions trapped in Qz1, Qz2 and Qz5 from V1, V2 and V4 veins are compatible with both magmatic and metamorphic fluid sources, as suggested by Böhlke and Irwin (1992) for the Oriental deposit in California (1.2–2.4×10^{-3}).

400   Similar Br/Cl ratios have been determined for fluid inclusions in samples of post-metamorphic gold quartz veins from the

401   Monte Rosa gold district, NW Italy (Diamond 1993) and the Muruntau gold deposit, Uzbekistan (Graupner et al. 2006).

Major and trace element distribution in fluid inclusions

403   Most previous workers investigating orogenic gold deposits (Diamond 1993; McCuaig and Kerrich 1998; Ridley and

404   Diamond 2000; Mernagh et al. 2007) have used microthermometric and spectroscopic methods of fluid inclusions to

405   determine the composition of ore-forming hydrothermal fluids. However, there are limited LA-ICP-MS data for fluid

406   inclusions of orogenic gold deposits and/or metamorphic fluids (Marsala et al. 2013; Rauchenstein-Martinek 2014,

407   2016; Morales et al. 2016, Fusswinkel et al. 2017).

408   Chemical analysis of FIAs (Fig. 8) shows that the major elements are essentially constant for different FIAs in all vein

409   types, suggesting that fluids were trapped under rock-buffered conditions. Alkali and alkali-earth element concentrations are

410   similar to those obtained from other orogenic gold deposits (Diamond 1993; Wagner et al. 2016). Mono- and divalent cations

411   such as Na, K, Ca and Mg are responsible for lower eutectic temperatures in comparison to fluids containing only Na

412   (Borisenko 1977). Low to moderate salinities, order of abundance Na>K>Ca>Mg, are typical in orogenic gold deposits

413   (Yardley and Bodnar 2014; Ribeiro et al. 2015; Morales et al. 2016). Figure 8 shows a significant Na dominance in all vein

414   types, with Mg and Ca increase in V2 veins (ESM-5). The concentrations of alkali-earth elements Sr and Ba are lower

415   compared to alkali elements, varying among quartz vein types (Fig. 8). Carbonate alteration of andesite may have acted as a

416   predominant process to influence fluid composition, resulting in significant Ca, Ba and Sr concentrations, which further

417   influenced the geochemistry of fluid inclusions in V1 shear, V2 extensional, as well as late-stage V4 veins (Kojonen et al.

418   1993; McCuaig and Kerrich 1998; Xavier et al. 2000). Alternatively, these elements may have been contributed to the fluid

419   due to interaction with surrounding carbonaceous pelites, containing high contents of Sr (up to 183 ppm) and Ba (up to 279

420   ppm; Ribeiro-Rodrigues 1998). Sodium and K metasomatism may have also been important, as well as formation of

421   hydrothermal alteration minerals such as sericite that indicates K enrichment in the fluid (Ridley and Diamond 2000; Morales

422   et al. 2016). In general, fluid-rock interaction resulted in Na decrease and Mg increase in V2 relative to V1 and V3 veins (Fig.

423   10a), whereas Sr increases in V2, V3 and V4 relative to V1 veins (Fig. 10b). A decrease of K from V1 to V2 and elevated Ca

424   relative to Sr and K in V2 veins compared to V1 shear veins (Fig. 10c), can be observed.

425   Figure 7 shows a continous As increase in FIAs from V1, through V2 and to V4 veins (ESM-3). During the early stage with

426   V1 vein formation, As in hydrothermal fluids fluctuated from relatively low to high values (fields 1 and 2 in Fig. 7). During

427   V2 and V4 formation a fluid richer in As evolved (fields 3, 4 and 5; Fig. 7; ESM-4). It is noteworthy that As-rich pyrite and

428 not arsenopyrite, is the As-bearing sulphide phase of the hydrothermal alteration in the andesite hosting the VQZ ore body

429 (Kresse et al. 2018).

430 According to Rauchenstein-Martinek et al. (2014, 2016), metamorphic fluids are commonly undersaturated in gold. Fluid

431 inclusions trapped in quartz-tourmaline-carbonate veins of the Sigma orogenic gold deposit show a range between 0.5 and

432 5.0 ppm Au (Garofalo et al. 2014). The present results display median values from 12 ppm in V1, 7 ppm in V2 and up to 29

433 ppm Au in the V4 late-stage veins (ESM-4; Fig. 7), suggesting that peak gold precipitation took place during the V1 and V2

434 vein development. Formation of the pyrrhotite-dominated V4 vein may have resulted from progressive decrease in sulphur

435 fugacity, which enabled pyrrhotite and not pyrite to form in the late stage of hydrothermal alteration. Lower sulphur fugacity

436 conditions may have hindered gold buffering and precipitation during V4 vein formation. Although the lowest Au

437 concentrations (1–4 ppm) are accompanied by low (17 ppm) to high (300 ppm) As concentrations in FIAs of the Qz1-V1

438 shear veins, all low, intermediate and high Au values (7–14 ppm) in Qz2-V2 extensional veins plot in the intermediate to high

439 As field (80–330 ppm). The Au-As correlation of V4 is highly variable, but the highest Au concentrations (56 ppm) is related

440 to high (120 ppm) As values. During V1 development As was partly supplied to form the early-stage As-rich pyrite only in

441 andesite, but remained in the fluid, i.e., did not precipitate to form arsenopyrite during the V2 and V4 late-stage vein formation,

442 which is evidenced by the absence of arsenopyrite.

443 **Characteristics of the ore-forming fluids**

444 **Fluid precipitation processes** Aqueous and aqueous-carbonic FIAs trapped in different quartz and vein types in the andesite-

445 hosted VQZ ore body contain a vapour phase of $\pm$ 10 vol%, indicating homogenous fluids (miscible) at the time of trapping.

446 Given that only fluid inclusions trapped in aqueous FIA 2_D in Qz2-V2 extensional veins display homogenisation into vapour,

447 but decripitate before final homogenisation, the evidence for intermittent phase immiscibility as a possible fluid precipitation

448 process is equivocal. According to Anderson et al. (1992), a positive correlation between Th_{TOT} and salinity is compelling

449 evidence for fluid mixing of two or more distinct miscible fluids. Based on the distribution of data in Figure 6a-c, the evidence

450 for mixing is vague. Hydrothermal fluids at Cuiabá either unmixed at a deeper crustal level, with the low-density CO_2 vapour-

451 rich fluid inclusions escaping to surface, or alternatively heterogeneous fluids with varying CO_2 and/or CH_4 proportions

452 moved up fault zones and cooled according to the local geothermal gradient.

453 **Evolution of volatiles in veins associated with wall rock reactions** Laser Raman data and their quantification show variable

454 amounts of CH_4 (8.6–41 mol%), CO_2 (30–91 mol%) and N_2 (28 mol%) in the non-aqueous phase of individual FIAs trapped

455 in Qz1-V1, Qz3-V3 and Qz5-V4 (except CO_2 is lacking in Qz2-V2 veins). Methane and CO_2 trapped in fluid inclusions from

gold-bearing veins are common in orogenic gold systems (Ho et al. 1985) and can be explained by either metamorphic reactions involving carbonates with H_2, as well as serpentinisation reactions (Xavier et al. 2000; Gaboury 2013, 2019). Nitrogen, in contrast, is only rarely detected and therefore the significant amount of N_2 in aqueous-carbonic FIAs trapped in the Qz3-V3 extensional vein arrays requires an explanation. Various authors (e.g. Andersen et al. 1993) provided evidence that N_2 can be sourced by: (i) breakdown of organic matter from sedimentary rocks where N_2 can be fixed in K-bearing silicates (mica), (ii) hydrothermal alteration of NH_4^+-bearing silicates and formation of N_2, or (iii) primary N_2 liberated from magma or through metamorphism of the lower crust.

Fluid source Low to moderate salinities (max 15 wt% NaCl equiv.) and moderate to high homogenisation and decrepitation temperatures of up to ~380°C (Fig. 6; Tables 4 and 5) of the ore-forming hydrothermal fluids are compatible with those associated with mesozonal orogenic gold deposits (Ridley and Diamond 2000; Goldfarb and Groves 2015; Groves et al. 2019). Stable isotope data at Cuiabá are consistent with the hydrothermal fluids being dominantly of metamorphic origin (Lobato et al. 2001c) based on: (i) oxygen isotope data on carbonates of the Cuiabá BIF and andesite range between +9 and +10 ‰, which are compatible with metamorphic fluids (Taylor 1987); (ii) $\delta^{34}S$ signature of pyrite and pyrrhotite ranges between 1.4 and 5.6 ‰ (Lobato et al. 2001c; Kresse et al. 2018), indicating a sedimentary sulphur source (Farquhar et al. 2000); (iii) carbon isotope data on carbonate minerals of the Cuiabá BIF and andesite are in the range of 0.7 to-8.5 ‰ and -5.5 to -8.4 ‰, respectively, which are similar to other Archaean greenstone belt-hosted orogenic gold deposits worldwide (De Ronde et al. 1997) and those are interpreted of metamorphic origin. Kresse et al. (2018) conducted sulphur isotope analyses on hydrothermal pyrite and concluded that sedimentary rocks were a significant source for sulphur. Sedimentary rocks make-up much of the local stratigraphy in the Rio das Velhas greenstone belt. Studies on the metasedimentary schist-hosted Macraes orogenic gold deposit in the Otago goldfield by Craw and MacKenzie (2016) have shown that this narrow range in oxygen isotope values is characteristic of hydrothermal fluids that have interacted with schistose host rocks and is widespread in hydrothermal systems throughout the Otago schist belt.

Significance of base metal concentrations

Cuiabá is low in base metal minerals, which is compatible with orogenic gold systems (Phillips and Powell 2010; Goldfarb and Groves 2015). Typical low-salinity metamorphic fluids are unlikely candidates for forming large base metal occurences and have average Zn, Pb and Cu values in the range of 1–10 ppm (Phillips and Powell 2010; Wagner et al. 2016). The FIAs in the Cuiabá vein system have elevated Zn, Pb and Cu concentrations in comparison to sedimentary systems. However, our data are compatible with the predominance of metamorphic fluids.

484   Anomalous base metal contents are also registered in pyrite hosted in BIF, andesite and carbonaceous pelite within the

485   Cuiabá deposit (Fig. 2) (Kresse et al. 2018), a feature equally reported by Oliver et al. (2015) for the Neoproterozoic Paracatu

486   sedimentary rock (black shale)-hosted orogenic gold deposit. The sulphur isotope ratios obtained for pyrite and pyrrhotite by

487   Kresse et al. (2018) indicate that the metamorphic hydrothermal fluids (Fig. 12) interacted and exchanged chemical

488   components with the sedimentary rocks in the Cuiabá area during their ascent. Two scenarios may be envisaged: equilibration

489   with the wall rocks and -or mixing with basinal brines originating from sedimentary, as suggested by Pb and Sr isotope studies

490   on pyrite at Cuiabá. However, the salinity data are not compatible with this latter hypothesis. Lead isotope analyses of sulphide

491   minerals show a limited spread of data (Lobato et al. 2001b, c), indicating the formation of gold mineralisation during the late

492   Neoarchaean between 2.75 and 2.70 Ga. Although the interpretation of Pb isotope data is uncertain (Lobato et al. 2001c), Pb

493   values may imply a derivation from a mixture of old continental crust and greenstone belt sedimentary rocks (Noce et al.

494   2007). Existing Sr isotope data ($^{87}Sr/^{86}Sr$) of BIF-hosted pyrite from the Cuiabá deposit support the influence of the continental

495   crust related to the fluid geochemistry (Lobato et al. 2001c). As Archaean fluids are typically characterised by low Sr isotope

496   ratios, the recorded relatively high ratio of 0.707909 may indicate that Sr of the mineralising fluids was derived from the

497   upper continental crust (Lobato et al. 2001a, b; Noce et al. 2007).

498   The geochemical data set of FIAs at Cuiabá, Lamego and Córrego do Sítio in the QF (Fig. 1) demonstrate that the major and

499   trace element compositions are nearly identical with few discrepancies such as Cu, Pb, Ag and Au (Morales et al. 2016). The

500   Lamego and Córrego do Sítio deposits show elevated base metal concentrations from 100 to 1,000 ppm (Fig. 11; Table7).

501   The Cuiabá Th$_{TRAP}$ and moderate salinity data obtained in all vein types correlate positively with higher base metal

502   concentrations than typically encountered in orogenic gold deposits (Table 7). Minimum Th$_{TRAP}$ in similar salinity ranges are

503   obtained for Lamego (200–370°C) and Córrego do Sítio (310–395°C) (Ribeiro et al. 2015; Morales et al. 2016).

504   Taking these data into account (Fig. 11; Table 7), it appears that FIAs trapped in shear and extensional veins at Cuiabá,

505   Lamego and Córrego do Sítio display significant base metal concentrations in comparison to data of metamorphic fluids

506   related to orogenic belts elsewhere (Marsala et al. 2013; Rauchenstein-Martinek et al. 2014, 2016; Wagner et al. 2016) and

507   orogenic gold deposits in general (Fusswinkel et al. 2017).

508   Sedimentary rocks may be considered as an essential source of gold and fluids (Pitcairn et al. 2006; Large et al. 2011), whereby

509   the BIF-surrounding carbonaceous pelite may represent a possible source for base metals (Fig. 2a). Large et al. (2011)

510   indicated that metalliferous black shales are commonly enriched in metals including Mo, V, Ni, Cr, Zn, As, Cu and Pb. Xavier

511   et al. (2000) and Lobato et al. (2001b) show the relevance of carbonaceous pelite and fluid-rock interactions for some Rio das

512   Velhas greenstone-belt-hosted deposits. Morales et al. (2016) highlights the carbonaceous pelites at the Córrego do Sítio

513   district and Cuiabá deposits as a partial sources of metals; however, these units only amount to a minor portion of their rock

514   packages. Whole-rock geochemical analyses of carbonaceous pelites at Cuiabá yield Zn values up to 630 ppm, Pb in the order

515   of 56 ppm and As reach up to 162 ppm (Ribeiro-Rodrigues 1998). Andesite reveals Zn, Pb and As concentrations of 218 ppm,

516   16 ppm and 15 ppm, respectively. Gold concentrations in carbonaceous pelites and andesite are between 8–10 ppb. Based on

517   data of Baltazar and Zucchetti (2007), Martins et al. (2016) calculated an approximate thickness of 5,550 m of clastic, clastic-

518   chemical and volcaniclastic sedimentary rocks, making the Rio das Velhas a sedimentary-rich greenstone belt. The Archaean

519   Cuiabá orogenic gold deposit is over- and underlain by these thick sequences of lithologically variable, supracrustal

520   sedimentary rocks. Sedimentary rocks composed of widespread turbidites (Burwash-Wash Formations; Taylor and McLennan

521   1985) also dominate similar Archaean terrains, such as the Yellowknife Supergroup (Helmstaedt and Padgham 1986). These

522   contrast with other volcanic-dominated greenstone belts and associated orogenic gold deposits (Anhaeusser 2014).

523   **Cuiabá vein and fluid model**

524   The proposed model for hydrothermal fluid flow and precipitation of metals, including gold, at the Cuiabá deposit is based

525   on the detailed investigation of the andesite shear-zone-hosted quartz veins and the physico-chemical constraints obtained by

526   the present fluid inclusion investigation. We propose a two-step hydrothermal model that involves the development of: 1) V1

527   to V3 veins by an early-stage, aqueous-carbonic, high temperature fluid, with minimum Th_{TRAP} at 290°C (Qz2-V3) to a

528   maximum Th_{TRAP} at 360°C (Qz1-V1) and 2) breccias-style V4 veins, which formed by an evolved, late-stage, aqueous-

529   carbonic, low temperature fluid with a mean Th_{TRAP} at 260°C. The evolution of the vein system, including the hydrothermal

530   fluids and gold mineralisation, is illustrated in Figure 12 and given in the following section. Overall, the two-step hydrothermal

531   fluid model is interpreted to reflect four pulses of hydrothermal fluids during the evolution of the paleohydrothermal system.

532   Fluid pulse 1 to 3 relate to the first hydrothermal stage, whereas fluid pulse 4 relates to the second hydrothermal stage (Fig.

533   12). The first hydrothermal stage contains:

534   **Pulse 1** An early, first hydrothermal fluid pulse is represented by Na-K-rich, aqueous and aqueous-carbonic FIAs of low and

535   moderate salinity with $CO_2 > CH_4$ (N_2 free) (Fig. 12). These oxidised fluids have base metal contents between 60 to 1,600

536   ppm and median As and Au values of 64 ppm and 12 ppm, respectively. They are trapped in Qz1-V1 shear and Qz1-V2

537   extensional veins (the veins with visible gold), with mean Th_{TRAP} between 350 and 380°C. These temperatures are similar to

538   the arsenopyrite formation temperature between 300 and 390°C (Kresse 2018).

Pulse 2 The second hydrothermal fluid pulse is represented by aqueous FIAs of moderate-salinity (Fig. 12). These are Mg-Ca-Sr-Ba-rich and Na-K-poor, with base metal contents between 200 and 600 ppm and median As (125 ppm) and medium Au (7 ppm) values. These are trapped in Qz2-V2 extensional veins with Th_{TRAP} ranging from 290 to 360°C.

Pulse 3 The third hydrothermal fluid pulse is base metal rich and represented by Na-K-Ca-rich, aqueous and aqueous-carbonic FIAs of low and moderate salinity and $CH_4 > CO_2 = N_2$ (Fig. 12). The base metal content ranges from 300 to 1,500 ppm and FIAs trapped in Qz3-V3 extensional vein arrays have Th_{TRAP} between 290 and 340°C.

The second hydrothermal stage includes:

Pulse 4 The forth hydrothermal pulse is characterised by aqueous and aqueous-carbonic FIAs of low and moderate salinity (Figs. 6, 12). It is Na-K-rich, displays elevated Ca, Sr and Ba values and shows base metal contents between 100 and 1,000 ppm with very high median As (290 ppm) and Au (29 ppm) values. Pulse 4 fluids are trapped in Qz5-V4 extensional, breccias-style veins with significant lower Th_{TRAP} between 240 and 270°C when compared to the other fluid pulses.

The low to moderate saline, aqueous-carbonic fluid of Pulse 1 is suggested to represent the main mineralising fluid in V1 shear and V2 extensional veins, which led to gold precipitation. Since fluid inclusions in V1 shear veins, as well as in V2, V3 and V4 extensional veins, are very similar with regards to compositional types and physico-chemical conditions, the fluid chemistry probably did not change significantly from the first (Pulses 1–3) to the second (Pulse 4) hydrothermal stage during the Archaean deformation history. The Au concentration in FIAs trapped in each vein type (Qz1-V1 shear, Qz2-V2 extensional, Qz5-V4 late-stage veins) suggest the following: 1) an early precipitation of Au as native gold from a Na-K-As-rich hydrothermal fluid due to intermittent phase immiscibility at depth and/or partial mixing and 2) a late-stage Au-bearing Na-K-As rich hydrothermal fluid, which was not able to precipitate gold in pyrrhotite-rich V4 late-stage veins probably due to insufficient total concentration of sulphur ($m_{\sum S}$).

Conclusions

The detailed investigations on hydrothermal fluids in the different vein types at Cuiabá revealed the following:

1. The Cuiabá quartz veins, hosted in the footwall andesite of the Veio de Quartzo ore body, encompass V1 shear, V2 extensional (V1 and V2 with visible gold), V3 extensional vein array and V4 extensional (breccias-style) veins. An early-stage, anhedral Qz1 evolves to a granoblastic Qz2 and a late-stage, euhedral Qz3 during a first hydrothermal stage, which is represented by V1, V2 and V3 veins. The breccia-style V4 veins are interpreted to be related to a second hydrothermal stage, during which the anhedral Qz5 develops, bearing morphological and fluid inclusion characteristics similar to Qz1.

2. Microthermometric data show that the ore-forming fluid have the signature of typical orogenic gold fluids, i.e., low- to moderate-salinity (4.0–10.0, locally up to 15 wt% NaCl equiv.) containing variable amounts of CO_2, CH_4, N_2 and minor HS^-.

3. The geochemical data in FIAs display the following fluid-rock interactions inbetween quartz veins: (i) Na decreases in V2 relative to V1 and V3 veins; (ii) Sr increases in V3 and V2 relative to V1; (iii) K continously decreases from V1 to V4; and (iv) Ca is relatively higher to Na and K concentrations in V2 in comparison to V1, V3 and V4.

4. Possible intermittent phase immiscibility as well as heterogeneous entrapment resulting from intermittent partial mixing of two or more ore fluids may be considered as the principal fluid processes leading to the formation of the Cuiabá orogenic gold deposit.

5. A distinction to the typical orogenic gold fluids is the Cu, Zn and Pb enrichment encountered in fluid inclusions of Cuiabá, which are also similar to other deposits hosted in the Rio das Velhas greenstone belt (Lamego and Córrego do Sítio). These values, in the range of 100 to 1,000 ppm, may have been caused by interaction with: (i) metalliferous black shales and (ii) the (meta) sedimentary rocks that dominate the Rio das Velhas greenstone belt.

6. The fluid inclusion results provide an opportunity to classify shear and extensional veins and help identifying the evolution of the fluids forming the different vein types in the orogenic gold deposits of the QF. The similar geochemical affinity of the Cuiabá veins, hosted in the footwall andesite, suggest they are all part of the same hydrothermal event. This event is characterised by two main stages, with the first displaying changing physico-chemical parameters due to fluid-rock reactions and fluid dynamic processes. This is particularly apparent in the recorded Au concentrations of FIAs trapped in the main hosts for the mineralisation of the VQZ ore body (Qz1-V1 shear and Qz2-V2 extensional veins), but also in the Qz5-V4 late-stage veins, which may represent a paragenetically late and second Archaean hydrothermal fluid stage.

808   (Level 15, VQZ ore body)

809   **Fig. 4** Photomicrographs of quartz types. **a** Qz1 and Qz2 of V1 shear veins (transmitted light) (sample 009_7). **b** Qz1 and

810   Qz2 of V1 shear veins (transmitted light, crossed nicols) (sample 009_7). **c** Intergrowth of all quartz types of V1 shear and

811   V3 extensional vein arrays (transmitted light) (sample FICU01). **d** Qz5 of V4 late-stage veins (transmitted light) (sample

812   QZL_1).

813   **Fig. 5** Representative FIAs of all vein types, Veio de Quartzo ore body. **a-d** Qz1-V1 shear veins with small-sized, two-phase

814   aqueous (FIA8$_A$) and aqueous-carbonic(FIA8$_C$) grouped FIAs. **e-g** Qz2-V2 and Qz2-V3 extensional veins showing, two-

815   phase, aqueous, FIAs (FIA 2$_E$, FIA 11$_A$, FIA 11$_C$). **h-j** Qz3-V3 extensional vein arrays displaying two-phase, grouped aqueous

816   fluid inclusion (FIA4$_A$) and two-phase, individual, aqueous-carbonic fluid inclusions (FIA 4$_C$) and internal trail of two-phase,

817   aqueous fluid inclusions (FIA 6). Photomicrographs taken under transmitted light

818   **Fig. 6** Box and whisker plots of salinity (a), Th$_{TOT}$ (b), T$_{DECREP}$ (c) and Th$_{TRAP}$ (d) for analysed FIAs. The central box is the

819   middle 50% of the data from 25% quartile (Q1) to 75% quartile (Q3); whiskers are extreme values that are not outliers. Circles

820   indicate outlier values. Isochore diagram (d) of aqueous and aqueous-carbonic FIAs. The range of P$_{min}$ and P$_{max}$ are calculated

821 based on the intersection points with the mean Th$_{TRAP}$ and calculated arsenopyrite formation temperature (Kresse 2018). The

822 bluish area indicates metamorphic greenschist facies conditions (Spear 1995)

823 **Fig. 7** Gold vs. As plot showing low to moderate saline, aqueous two-phase FIAs trapped in Qz1-V1 shear, Qz2-V2

824 extensional and Qz5-V4 late-stage veins. Error bars (SD) are given in both directions (dashed lines). The arrow indicates the

825 development of increasing Au and As concentrations in fluid inclusions of Qz1-V1 shear veins, through Qz2-V2 extensional

826 veins to maximum Au values of Qz5-V4 late-stage veins. A and B represent populations of V1 shear veins

827 **Fig. 8** Laser ablation ICP-MS results in ppm as whisker box plots for all different vein types analysed. Qz1-V1 shear, Qz2-

828 V2 extensional, Qz3-V3 extensional vein arrays, Qz5-V4 late-stage veins. The central box is the middle 50% of the data from

829 25% quartile (Q1) to 75% quartile (Q3); whiskers are extreme values that are not outliers. Circles indicate outlier values

830 **Fig. 9** Crushed-leach ion chromatography in fluid inclusions trapped in vein quartz of the andesite-hosted Veio de Quartzo

831 ore body. **a** Cl/Br vs. Na/Br molar ratio.Qz2V2 veins lie close to the seawater evaporation line, whereas those of the Qz3-V3

832 far above this line (inset), indicating that significant locally exchange of Na for other cations has taken place. Precipitation or

833 dissolution of halite produces a trajectory parallel to the 1:1 line (inset). The field for the ultramafic-hosted Pampalo orogenic

834 Au deposit (Fusswinkel et al. 2017), of low salinity, aqueous fluids of Alpine quartz veins (Leisen et al. 2012) is also shown.

835 Note that analyses are not charged balanced and therefore data plot well to the left of the line in diagram. **b** Br/Cl ($\times$ 1,000)

836 molar ratio vs. Cl concentration**.** Greyish band shows the range of mantle/magmatic fluid ratios based on values by Jambon

837 et al. (1995)

838 **Fig. 10** Normative plots of alkali and alkali-earth elements of LA- ICP-MS analyses from aqueous and aqueous-carbonic

839 FIAs of V1 shear, V2 extensional, V3 extensional vein array and V4 late-stage vein. **a** Na-Mg-K, **b** Ba-K-Sr **and c** Ca-K-Sr.

840 The Na- and K-rich fluid (V1 shear veins) evolved to a Mg-Sr-Ca-rich and Na-poor fluid (V2 extensional veins). New Na-

841 and K-rich fluid is related to the V4 late-stage vein. The V3 extensional vein arrays, immersed in the V1 shear vein type, show

842 similar composition to V1

843 **Fig. 11** Correlation plot of Zn-Pb and Zn-Cu concentrations of different types of crustal fluids in comparison with fluid

844 inclusion LA-ICP-MS data of the andesite-hosted quartz veins at the Cuiabá deposit. References: Lamego orogenic Au deposit

872 Veio de Quartzo ore body

873

874 **Table 1** Classification of the Cuiabá quartz veins (adapted after Vitorino 2017)

Vein type Classification after Passchier (2001) and Robert and Poulsen (2001)	Vein system	Controlled by	Mineralogical composition		Vein geometry
			Main	**Accessory**	
Fault-fill	V1 (shear)	S$_m$	Qz1, Qz2, cb, ser, chl, plg	py, po, cpy, sph, free gold	Folded, pinch and swell, boudins
a- Extensional b- Oblique extensional c- Fault-fill	V2 (a, b, c) (extensional)	S$_b$	Qz2, Qz1, cb, ser, chl	py, po, cpy, (free gold)	Tabular and folded; boudins and sigma shapes
Extensional vein array	V3 (extensional)	S$_m$	Qz3, Qz4	-	En-echelon
Extensional and brecciated	V4 (late-stage, extensional)	Flanking and cross-cutting S$_m$	Qz5, cb	py and po	Tabular and massive

875 Abbreviations: qz = quartz, cb =carbonate, ser = sericite, chl = chlorite, plg =plagioclase, py = pyrite, po = pyrrhotite, cpy =
876 chalcopyrite, sph = sphalerite
877

878 **Table 2** Summary of FIAs and their characteristics (e.g., chemical system, L/V ratio, shape, size and occurrence) based on
879 quartz and vein types[1]

Vein type	Sample ID	Qz type	FIA	N	Chemical system	L/V ratio	Shape	Size(in µm)	Occurrence
V1 shear veins	009_7	Qz1	7	5	aq	10	Ovoid shaped and negative crystal	5–10	Grouped
		Qz1	8$_A$	5	aq	10	Irregular to ovoid shaped	5–10	Grouped
		Qz1	8$_B$	3	aq	10	Irregular to ovoid shaped	5–10	Grouped
		Qz1	8$_C$	4	aq-carb	10	Irregular to ovoid shaped	5–10	Grouped
		Qz1	8$_D$	2	aq	10	Irregular to ovoid shaped	5–10	Grouped
		Qz1	8$_E$	2	aq-carb	10	Irregular to ovoid shaped	5–10	Grouped
	007_2	Qz1	10	3	aq-carb	10	Negative crystal	5–10	Isolated

V2 extensional veins		Qz2	9	5	aq	10	Regular to ovoid shaped	5–10	Isolated
		Qz2	11$_A$	7	aq	10	Regular to ovoid shaped		Grouped
		Qz2	11$_B$	3	aq	10	Regular to ovoid shaped	5–10	Grouped
		Qz2	11$_C$	5	aq	10	Regular to ovoid shaped	5–10	Grouped
		Qz2	11$_D$	8	aq	10	Regular to ovoid shaped	5–10	Grouped
		Qz2	11$_E$	5	aq	10	Regular to ovoid shaped	5–10	Grouped
V3 extensional vein arrays	FICU01	Qz1	1$_A$	4	aq	10	Irregular to ovoid shaped	5–10	Grouped
		Qz1	1$_B$	7	aq	10	Irregular to ovoid shaped	5–10	Grouped
		Qz2	2$_A$	5	aq	10*	Irregular to ovoid shaped	5–10	Grouped
		Qz2	2$_B$	4	aq	10	Regular to ovoid shaped	5–10	Grouped
		Qz2	2$_C$	4	aq	10	Regular to ovoid shaped	5–10	Grouped
		Qz2	2$_D$	3	aq	10	Regular to ovoid shaped	5–10	Grouped
		Qz2	2$_E$	6	aq	10	Regular to ovoid shaped	5–10	Grouped
		Qz2	2$_F$	4	aq	10	Regular to ovoid shaped	5–10	Grouped
		Qz2	2$_G$	7	aq	10	Regular to ovoid shaped	5–10	Grouped
		Qz2	3	6	aq	10	Regular	5–10	Isolated
		Qz3	4$_A$	3	aq	10	Regular	5–15	Grouped
		Qz3	4$_B$	1	aq-carb	10	Regular to ovoid shaped	5–15	Isolated
		Qz3	4$_C$	2	aq-carb	10	Regular	5–15	Isolated
		Qz3	4$_D$	3	aq-carb	10	Ovoid shaped to irregular	10–20	Isolated
		Qz3	5$_A$	5	aq	10	Irregular	5–15	Grouped
		Qz3	5$_B$	4	aq	10	Irregular	5–10	Isolated
		Qz3	6	5	aq	10	Regular to ovoid shaped	5–15	Internaltrail
V4 late-stage veins	QZL_1	Qz5	12$_A$	6	aq	10	Regular to ovoid shaped	10–20	Grouped
		Qz5	12$_B$	2	aq-carb	10	Regular to ovoid shaped	10–15	Isolated
		Qz5	13	4	aq	10	Irregular	10–15	Isolated
		Qz5	14	7	aq	10	Regular ovoid shaped	10–15	Grouped
		Qz5	15	5	aq	10	Regular	5–15	Grouped
		Qz5	16$_A$	6	aq	10	Ovoid shaped to irregular	10–15	Isolated
		Qz5	16$_B$	5	aq	10	Ovoid shaped to irregular	5–15	Grouped
		Qz5	16$_C$	2	aq-carb	10	Ovoid shaped to irregular	5–15	Isolated
		Qz5	16$_D$	3	aq	10	Ovoid shaped to irregular	10–15	Grouped
		Qz5	17$_A$	2	aq	10	Ovoid shaped	5–10	Grouped
		Qz5	17$_B$	2	aq-carb	10	Ovoid shaped	10–15	Isolated
		Qz5	18	8	aq	10	Ovoid shaped to irregular	5–15	Grouped
		Qz5	19	2	aq	10	Ovoid shaped to irregular	5–10	Isolated
		Qz5	20	8	aq	10	Ovoid shaped to irregular	5–15	Grouped

880 Abbreviations: Qz = quartz, N=number

881 [1]Sample FICU01 mainly consists of Qz3, but also describes Qz1 and Qz2, both corresponding to the V1 shear vein type.

Table 3 Summary of microthermometry results and calculated salinity values of aqueous FIAs trapped in quartz of andesite-hosted veins[1]

Sample ID	Vein type	Quartz type	FI phase	FIA	N	Min-Max Tm_{ice}	Min-Max Th_{TOT} [°C]	Min-Max T_{DECREP} [°C]	Min-Max salinity [wt% NaCl equiv.] (average salinity value)
009_7 3e	V1 shear veins	Qz1	Laq + Vaq	8_A	5	−3.5 to −1.1	-	220 to 250 (into L)	1.8 to 5.6 (3.8)
009_7 3b		Qz1	Laq + Vaq	8_B	3	−3.4	-	230 to 240	5.4
009_7 3b		Qz1	Laq + Vaq	8_D	4	−9.5 to −5.2	-	-	8.1 to 13.4 (12.4)
009_73a		Qz1	Laq + Vaq	7	5	−5.8 to −4.2	-	235 to 245	6.4 to 8.9
007_2 1a	V2 extensional veins	Qz2	Laq + Vaq	9	5	−5.2 to −3.3	-	325	5.0 to 8.5 (6.7)
007_2 1		Qz2	Laq + Vaq	11_A	7			-	
		Qz2	Laq + Vaq	11_B	3	−4.1 to −3.5	260 to 290 (into L)	-	4.5 to 6.6 (5.8)
		Qz2	Laq + Vaq	11_C	4			-	
007_2 3		Qz2	Laq + Vaq	11_D	8	−5.0 to −3.0	250 to 270 (into L)	-	4.9
		Qz2	Laq + Vaq	11_E	5		230 to 250 (into L)	-	8.0
FICU4a	V3 extensional vein arrays	Qz3	Laq + Vaq	4_A	3	−4.9 to −2.9	-	270	4.8 to 7.8 (6.6)
FICU3a		Qz3	Laq + Vaq	6	5	−6.2 to −3.9	-	350	6.2 to 9.5 (8.3)
FICU3b		Qz3	Laq + Vaq	5_A	5	−2.2 to −1.8	-	210/220/230	3.0 to 3.6
FICU3c		Qz3	Laq + Vaq	5_B	4	−6.3	-	-	9.2
FICU4d/e		Qz2	Laq + Vaq	3	6	−5.5 to −3.3	220 to 225 (into L)	270 to 320	5.5 to 8.5 (5.8)
FICU2a		Qz2	Laq + Vaq	2_A	5	−3.0	-	-	4.9

Notes: Numbering of FIA's starts with FIA 8 in V1 shear veins due to preparation progress

[1]Sample FICU1 mainly consists of Qz3, but is in conjunction with Qz1 and Qz2 of V1 shear vein

Table 4 Summary of microthermometry results and calculated clathrate salinity values of aqueous-carbonic FIAs trapped in quartz of andesite-hosted veins

Sample ID	Vein type	Quartz type	FI type	FIA	N	Min-Max Tm_{CO2}	Min-Max T_C [°C]	Min-Max Th_{CO2}	Min-Max T_{DECREP} [°C]	Min-Max salinity [wt% NaCl equiv.]
009_7 2	V1 shear veins	Qz1	Laq + Vcarb	8_C	4	–61.7 to –58.1	1.2 to 3.6	25.1 to 30.4	-	9.3 to 12.7
009_7 2		Qz1	Laq + Vcarb	8_E	3	–61.1 to –59.1	6.1 to 6.6	29.4 to 30.1	280 to 310 (into V)	7.2
007_2 2	V2 extensional veins	Qz1	Laq + Vcarb	10	3	-	15.2 to 16.8	-	215 to 275	-
FICU4b	V3 extensional vein arrays	Qz3	Laq + Vcarb	4_B	1	–57.4	6.8	-	-	6.0
FICU4c		Qz3	Laq + Vcarb	4_C	2	–57.4	0.4 to 3.6		-	9.2 to 15.1
FICU4c		Qz3	Laq + Vcarb	4_D	3	–61.0 to –57.2	3.0 to 6.5	28.4 to 30.1	220 to 290 (into V)	6.5 to 10.1 (8.2)
QZL 2b	V4 late-stage veins	Qz5	Laq + Vcarb	16_C	2	-	6.1 to 7.0	-	-	5.7 to 7.2 (6.4)
QZL 2c		Qz5	Laq + Vcarb	17_B	2	-	7.7 to 8.1	-	-	3.7 to 4.4
QZL 1a		Qz5	Laq + Vcarb	12_B	2	-	0.3 to 3.6	-	-	11.0 to 15.1

Table 5 Homogenisation, decrepitation and trapping temperatures based on pressure (temperature) correction of FIAs. Th$_{TRAP}$ from 300 to 360°C have a similar range as those of the arsenopyrite formation temperature (300–390°C) obtained from geothermometry in BIF-hosted arsenopyrite (Kresse 2018).

Vein type	FIA	Homogenisation temperature	Trapping temperature (*decrepitation temperature)
Qz1-V1	FIA 8$_{A-B}$	-	220–250°C*
	FIA 8$_E$	-	280–310°C*
Qz2-V3	FIA 2	220–230°C	290–300°C
	FIA 3	220–225°C	290–295°C
Qz2-V2	FIA 11$_{A-E}$	230–290°C	300–360°C
Qz3-V3	FIA 4$_D$	-	220–270°C*
Qz5-V4	FIA 15	175°C	245–265°C
	FIA 16$_B$	195°C	
	FIA 17$_A$	190°C	
	FIA 20	190°C	

Table 6 Ion chromatography analyses of fluid inclusions of quartz vein types of the andesite-hosted VQZ ore body

	V1 shear veins (Qz1)			V2 extensional veins (Qz2)		V3 extensional vein arrays (Qz3)		V4 late-stage veins (Qz5)
