Body-mounted accelerometers provide a new prospect for estimating power use in flying birds, as the signal varies with the two major kinematic determinants of aerodynamic power: wingbeat frequency and amplitude. Yet wingbeat frequency is sometimes used as a proxy for power output in isolation. There is, therefore, a need to understand which kinematic parameter birds vary and whether this is predicted by flight mode (e.g. accelerating, ascending/descending flight), speed or morphology. We investigate this using high-frequency acceleration data from (i) 14 species flying in the wild, (ii) two species flying in controlled conditions in a wind tunnel and (iii) a review of experimental and field studies. While wingbeat frequency and amplitude were positively correlated, R^2 values were generally low, supporting the idea that parameters can vary independently. Indeed, birds were more likely to modulate wingbeat amplitude for more energy-demanding flight modes, including climbing and take-off. Nonetheless, the striking

variability, even within species and flight types, highlights the complexity of describing the kinematic relationships, which appear sensitive to both the biological and physical context. Notwithstanding this, acceleration metrics that incorporate both kinematic parameters should be more robust proxies for power than wingbeat frequency alone.

1. Introduction

Factors affecting the energetic costs of flight can have a profound influence on the ecology and behaviour of birds, with flight conditions affecting the location of migratory flyways, and in particular cases, breeding success [1,2]. Yet at fine scales, disentangling the impact of the biological and physical environment on flight costs can be challenging, given that a range of factors often vary simultaneously. These include the topography birds are flying over, individual position within a flock [3,4] and social context [5,6], as well as factors that vary over longer timescales including the birds' immunological state [7], and physical factors such as wind speed, turbulence and air density [8–10]. High-frequency data from animal-attached loggers have proved powerful in this regard, as the signal from onboard accelerometers can be used to quantify second-by-second changes in wingbeat frequency [11–13], and potentially other kinematic parameters [14].

Power varies in a U-shaped fashion with flight speed (specifically the airspeed) for most flying birds [15–19], and wingbeat frequency seems to follow the same trend, although it is not always pronounced [6,19–23]. This explains why wingbeat frequency has been used as a proxy for flight costs in a range of ecological studies (e.g. [6,14]). However, wingbeat frequency also has limitations as a proxy for power requirements, because studies by Hedrick *et al.* [21] and Tobalske *et al.* [19] have shown that the minimum wingbeat frequency does not always coincide with the minimum power speed. In fact, it can occur at over twice the minimum power speed, which demonstrates that other kinematic parameters, such as wingbeat amplitude, stroke-plane angle and span ratio, can have an important role in modulating power output [24–27].

The major determinants of the aerodynamic power output of a flapping wing are the wingbeat frequency (f) and amplitude (A). In flapping flight, the resultant aerodynamic forces (lift, drag and thrust) acting on the wing are predominantly determined by the flow over each wing section at each time instant [28]. This is the combination of the flow due to the forward velocity of the bird and the flapping motion of the wing (wing velocity). The flow over the wing section can be controlled by the wing velocity, which solely depends on the wingbeat frequency and wingbeat amplitude [18]. The aerodynamic forces exerted on the wings are proportional to the square of the velocity, and the mechanical power output is proportional to the cube of the velocity [18]. Therefore, while the total resultant aerodynamic forces can be modulated by varying the wing planform and angle of attack during flight, modulating the flow velocity over each wing section has the major effect. The power can be shown to be proportional to the cube of both amplitude and frequency, if the product of wingbeat amplitude and frequency is substituted for velocity (as they both scale the same with velocity [29]):

$$\text{Power} \sim A^3 f^3.$$

Despite the importance of both wingbeat frequency and amplitude for overall power output, an overview of the scenarios under which birds modulate one or the other parameter is lacking. Indeed, examples from the literature suggest that the relationship may not be straightforward. Some studies show that birds vary their power output with little to no change in wingbeat frequency [30–32], whereas others report that wingbeat frequency varies with the power output while the amplitude is unaltered [20]. It is, therefore, unclear whether birds vary frequency or amplitude to modulate power according to their flight mode (e.g. hovering, climbing, manoeuvring or level flight) or morphology.

Power can theoretically be modulated either by a contribution from both wingbeat frequency and amplitude, or by changes to one or the other. What is clear is that a proxy for flight power should ideally integrate information on wingbeat frequency and amplitude to be widely applicable. Two related proxies for energy expenditure have been proposed using data from body-mounted accelerometers, both of which integrate information on stroke frequency and signal amplitude. Dynamic body acceleration (DBA) was proposed in 2006 as a metric that captures whole-body acceleration [33,34], and has been shown to vary with the energy expended by free-living auks [35] and cormorants [7] in flight. However, the precise relationship between the DBA signal and wingbeat kinematics is unknown. Spivey & Bishop [36] also established a theoretical framework of how body acceleration can be related to the biomechanical power output of flapping flight, using the root mean square values of heave and surge acceleration and wingbeat frequency. This assumes that the amplitude of the dorsoventral or 'heave' accelerometer measurements vary with the wingbeat amplitude [6]. However, similar to DBA, the relationship between body and wing motions, and how they covary over a wingbeat cycle, has not been established.

In this study, we examine the outlook for acceleration-based proxies for power use in flapping flight across species and contexts. Specifically, we (i) test how the output of body-mounted accelerometers varies with wingbeat amplitude, using a novel methodology, and (ii) assess whether birds preferentially use wingbeat frequency or amplitude to modulate their power output (or speed, as a related response) according to (a) their body mass or morphology and (b) their flight mode. We address this by reviewing the experimental literature, where wingbeat kinematics have largely been quantified using high-speed video, and by conducting further trials, where we equip 14 species of bird with body-mounted accelerometers to monitor their flight behaviour in the wild.

2. Methods

2.1. Wind tunnel trials: does the acceleration signal vary with wingbeat amplitude?

Movement of the wings results in movement of the body in the same axis. Greater wingbeat amplitudes should result in greater vertical accelerations of the body for a fixed wingbeat frequency. We examined these relationships using a body-mounted accelerometer and magnetometer, and a small neodymium boron magnet attached to the leading edge of the wing [37]. The geomagnetic signal strength in each axis varied throughout the wingbeat cycle as a function of the angle and distance to the magnet. We, therefore, calculated the vector sum from all three

Figure 1. Set-up of the tag (DD; containing an accelerometer and magnetometer) and magnet (highlighted by the red rectangle) on (a) a pigeon and (b) a dunlin.

magnetometer channels, which varied solely with the distance to the magnet, giving a clear peak per wingbeat cycle when the magnet was closest to the sensor. This allowed us to assess how the vertical body acceleration varied in relation to the maximum vector sum from the magnetometer (as a proxy for wingbeat amplitude) within the same wingbeat cycle.

Data were collected from two species flying at a range of speeds in large, low turbulence wind tunnels. In one set of trials, two pigeons (*Columba livia*) were equipped with Daily Diary (DD) data loggers (Wildbyte Technologies, Swansea University, UK), sampling acceleration at 150 Hz and magnetic field strength at 13 Hz. Each pigeon was equipped with two units: one on the upper back and another on the lower back. The logger at the top of the back was positioned close to the magnet, whereas the logger on the lower back was sufficiently far from the magnet not to be influenced by it (as determined in preliminary tests). The second logger allowed us to control for the potential influence of changing geomagnetic field strength on the magnetometer output (due to changes in bird trajectory). Loggers had dimensions of 22 mm × 15 mm × 9 mm and a total mass that was less than 3% of the bird body mass (3.4 g per logger and battery). A cylindrical neodymium boron magnet (8 mm × 2 mm, 0.19 g) was taped to the leading edge of the wing, close to the wing root (figure 1a). Both the loggers and the magnet were attached with micropore tape. Pigeons were flown at speeds between 12 and 18 m s⁻¹. Experiments were performed between 25 January 2019 and 1 February 2019 in the wind tunnel of the Max Planck Institute for Ornithology, Germany, under ethical approval Gz.: 55.2-1-54-2532-86-2015 granted by the government of Upper Bavaria (Sachgebiet 54—Verbraucherschutz, Veterinärwesen, 80538 München).

Further trials were conducted with a dunlin (*Calidris alpina*) in the wind tunnel at Lund University, Sweden, which has similar performance characteristics to the tunnel in Seewiesen [38]. A small neodymium magnet (4 mm × 2 mm, 0.02 g) was attached to the wing of the dunlin following the same procedure. A single unit logging tri-axial acceleration and magnetic field strength at 100 Hz (Technosmart Europe) was attached to the back of the dunlin with a backpack harness (figure 1b). The logger was 16 mm × 24 mm × 12 mm and weighed 2.6 g, equivalent to 4.8% of the bird's body mass. The dunlin was flown at a range of speeds for less than 10 min. Ethical permission for all wind tunnel trials was obtained from Swansea University AWERB, permit no. 030718/66.

2.2. Variation in the amplitude–frequency relationship across species

Data from birds flying in the wind tunnel were combined with acceleration data from a further 12 species of free-flying birds (table 1) to examine relationships between wingbeat frequency

and amplitude, and whether birds are more likely to use one parameter or the other to modulate their power output, according to their mass and morphology. Datasets were selected for inclusion according to whether tags were attached on the back, rather than the tail, to minimize the contribution of the angular motion of the bird to the acceleration signal, when the sensor is placed far from the centre of mass [47].

Morphological parameters including wing loading, wingspan, wing area and body mass were either measured directly and averaged (following [18]) or taken from the literature (table 1). We used wingspan rather than aspect ratio because there is a framework linking the former to wingbeat kinematics [18]. In order to assess the role of wing loading independently from body mass, we calculated the residuals of the linear regression between log(wing loading) and log(body mass) [48].

All birds flying in the wild were equipped with tags recording tri-axial acceleration at 40 Hz (except common guillemots and gannets, where the sampling rate was 50 Hz, and pigeons, where it was 180 Hz). An examination of accelerometer data revealed some slight variation in sampling rate between logger types (up to 3 Hz), which was accounted for in the calculation of wingbeat frequency. Tags were attached to the back feathers using Tesa tape [49] in all species apart from pigeons, where tags were attached via Velcro strips glued to the back feathers [3,50]. The total mass of the tag, including housing and attachments, was under 5% of bird body mass and 3% in most cases. See electronic supplementary material, table S1, for details of ethical permissions.

Episodes of flapping flight were identified visually from the acceleration data [51]. Only periods of consistent flapping, with no interruption or rapid changes in amplitude, were selected for the analysis of both wind tunnel and wild data, irrespective of the species. Wingbeat frequency and heave amplitude (amplitude of the vertical body acceleration within a wingbeat) were quantified using the following approach, which enabled the estimation of the period of individual wingbeats. Peaks in heave acceleration associated with the downstroke (figure 2) were identified by smoothing raw heave values over three to five data-points for all species except the guillemots, which did not require smoothing as their high wingbeat frequency resulted in a relatively clean signal. A second-order derivative was then applied to identify the positive-to-negative turning points. Peaks were marked when the differentials exceeded a threshold within five points of the turning point. Thresholds were manually selected for each flight bout so that they only captured wingbeat peaks, as characterized by high heave accelerations (around 2 g). The section between each marked peak was considered as one wingbeat cycle and used to determine the wingbeat period (frequency). The wingbeat frequency of the dynamic soaring birds (birds that extract energy by flying through the wind shear in the atmosphere) represents the frequency during the

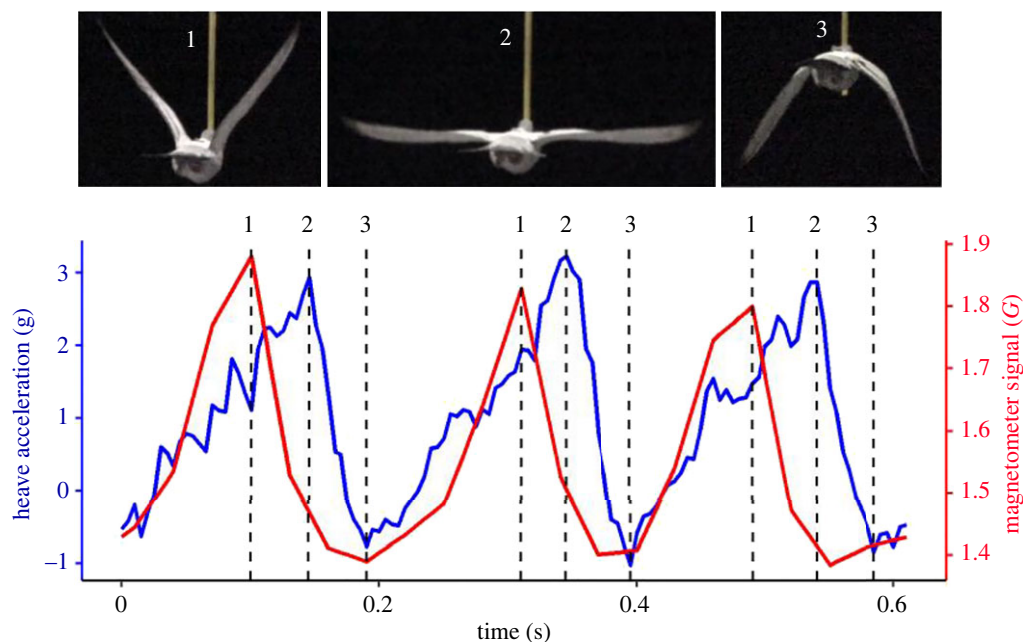

Figure 2. Comparison of the accelerometer (blue) and magnetometer (red) signals in the heave axis for three wingbeats from a pigeon flying in a wind tunnel at 15 m s^{-1} . (1) Peaks in the magnetometer signal correspond to the start of the downstroke (a smaller acceleration peak is sometimes evident at the same time), (2) peaks in the heave acceleration occur in the middle of the downstroke and (3) troughs in the magnetometer signal occur at the end of the downstroke. Images from the corresponding wingbeat cycle were captured using a Sony PXR-Z150 camera recording at 120 Hz, which was synchronized with the onboard logger by moving the equipped bird in view of the camera and a clock showing the logger time.

flapping period. The heave amplitude was calculated as the difference between the highest and lowest heave values within the wingbeat. Peak identification was conducted in R, v. 4.0.2 [52] using user-defined functions for Brünnich's guillemot, common guillemots, pigeons (homing flights only) and tropicbirds. All other data were processed using custom developed software DDMT (Wildbyte Technologies).

Filters were applied to remove unrealistic wingbeat frequencies. Low outliers were identified during short sections of non-flapping flights that were not excluded during the previous steps. High outliers were also recorded and were probably caused by false peak identification due to rapid manoeuvres. Filtered data were used to estimate final wingbeat frequencies, taken as the average over 10 consecutive wingbeats for wild data (which sometimes occurred in two flapping bouts for albatrosses) and five wingbeats for wind tunnel data (where the total wingbeats available from consistent flights was lower). Heave amplitude was also averaged over the same interval.

Finally, a simulation confirmed that our ability to estimate signal amplitude across species with variable wingbeat frequencies was not influenced by the sampling frequency (electronic supplementary material).

2.3. Variation in wingbeat kinematics with climb rate and airspeed

First, we examined how wingbeat frequency and signal amplitude varied in relation to airspeed for a pigeon flying in the wind tunnel (for which we had reliable records of airspeed). Then we assessed how pigeons, barn owls and tropicbirds varied their wingbeat frequency and amplitude in relation to airspeed and climb rate in the field. These datasets were selected due to the relatively high GPS sampling frequency (1 Hz for pigeons and barn owls, and once per minute for tropicbirds). Airspeed was estimated from the GPS-derived groundspeed and the wind vector [18], as recorded by a portable weather station (Kestrel 5500 L, Kestrel Instruments, USA) mounted on a 5 m pole (see [3]). The weather station was positioned at the

pigeons' release site, and at the highest point of Round Island (280 m.a.s.l.) in the case of the tropicbirds. For barn owls, weather data were collected from weather stations located near the nest sites. Altitude was calculated from barometric pressure recorded by the DD (at 4 Hz) in the case of the pigeons and tropicbirds, adjusted for daily changes in sea level pressure [3] and climb rate was calculated as the difference between consecutive values of altitude smoothed over 2 s. GPS altitude was used for the barn owls.

Airspeed, climb rate, wingbeat frequency and heave amplitude were averaged over 10 wingbeats for the pigeons and barn owls, and over 1-min intervals for the tropicbirds (to match the airspeeds). For each interval (10 wingbeats or 1 min) the proportion of level flapping flight was calculated, and only intervals with greater than or equal to 80% level flapping flight were included in the analysis.

Periods of level flapping flight were selected for the airspeed analysis, taking data where the rate of change of altitude was greater than -0.2 and less than 0.2 m s^{-1} . To minimize the variation in airspeed in the climb rate analysis, we excluded data with airspeeds higher or lower than the overall mean $\pm 1 \text{ s.d.}$

2.4. Statistical analysis

We used linear models to examine whether the peak heave acceleration increased with the peak magnetometer vectorial sum (as a proxy for wingbeat amplitude) for both dunlin and pigeon wind tunnel flights. We also used linear models to assess whether the heave amplitude varied with wingbeat frequency, using separate models for wind tunnel and wild flights.

To test whether birds varied their wingbeat amplitude to a greater extent than their wingbeat frequency in relation to climb rate and airspeed, we ran separate linear mixed-effects models (LMMs) per species (tropicbirds, barn owls and pigeons). These models included wingbeat amplitude as the response variable, expressed as a function of wingbeat frequency and the effect of either airspeed or climb rate on the slope of this relationship (the interaction between wingbeat frequency and either climb rate or airspeed). A positive interaction would indicate that

birds increased their amplitude more than frequency to increase speed/climb rate, while a negative relationship would indicate that they modulate wingbeat frequency more than amplitude. Individual was included as a random factor to account for uncontrolled variation relating to morphology and motivation (only one trip per bird was included). A continuous-time first-order autoregressive correlation structure was included in all models.

To investigate whether morphology affected the degree to which birds varied their wingbeat frequency, we calculated the coefficient of variation for the wingbeat frequency for each species, with the prediction that groups such as auks, with high wing loading, would be constrained in their range of frequencies. We did not run this analysis for the signal amplitude data, as the signal magnitude (and how this varies, e.g. with flight speed) might be influenced by factors including device location [47]. We used linear models and Pearson's product-moment correlation tests to see how the species-specific coefficients of variation (used as response variables) varied with wingspan, body mass, and residual wing loading. Note that pigeon flights recorded in the wind tunnel were not used in this analysis as free flight data had been recorded for pigeons. The dunlin flights were included. All statistical analyses were performed using R v. 4.0.2. LMMs were performed using the package 'nlme' (R v. 3.1-151 [53]). Model selection was performed using the package 'MuMIn' (R v. 1.43.17 [54]), and the distribution of residuals was tested using 'fitdistrplus' (R v. 1.1-5 [55]).

3. Results

3.1. Wind tunnel trials: does the acceleration signal vary with wingbeat amplitude?

Pronounced cyclic changes in the magnetometer signal were evident through the wingbeat cycle for both species that were flown in the wind tunnel (figure 2) due to the changing magnetic field strength driven by the small magnet attached to the leading edge of the wing. The magnetometer signal was highest at the start of the downstroke when the distance between the magnet and the transducer was at a minimum, and it decreased as the downstroke progressed, until the magnet was farthest from the logger at the end of the downstroke (figure 2). By contrast, the maximum heave acceleration occurred mid-downstroke when the wing traversed the body, corresponding to the point of maximal lift generation [56,57]. The magnetometer signal, therefore, varied with the wing displacement rather than wing (and body) acceleration, explaining why the peaks in magnetic and acceleration signals were offset from each other.

Nonetheless, we found a positive linear relationship between heave amplitude and the peak magnetometer vectorial sum in both species (pigeons: estimate = 1.253, s.e. = 1.02, t -value = 5.151, $p < 0.001$; dunlin: estimate = 2.639, s.e. = 0.085, t -value = 31.01, $p < 0.001$), showing that the body acceleration increases with wingbeat amplitude (figure 3).

3.2. Assessing the relationship between wingbeat amplitude and frequency

We then assessed how the wingbeat frequency and heave amplitude (as a proxy for wingbeat amplitude as established for pigeon and dunlin) covaried for different species. There was a positive, linear relationship between wingbeat

Figure 3. The heave amplitude increased with the maximum magnetometer vectorial sum within wingbeat cycles for (a) a dunlin and (b,c) two pigeons flying in wind tunnels across a range of flight speeds. The variation in absolute values from the magnetometer will vary due to the position of the magnet on the wing and its distance to the body-mounted magnetometer. The amplitude of the heave signal is influenced by the position of the back-mounted logger.

frequency and heave amplitude in almost all species that flew in the wild ($n = 13$) and the wind tunnel ($n = 2$) (table 2). The exceptions were three of the four birds that use dynamic soaring: the northern fulmar, grey-headed albatross and wandering albatross. Nonetheless, most R^2 values were relatively low, ranging from 0.001 to 0.38 (table 2).

We then examined the coefficient of variation (c.v.) in wingbeat frequency, to assess whether this varied with bird mass or morphology. These coefficients were calculated by pooling data from all individuals of the same species to cover the various flight conditions (e.g. wind speeds) experienced across tracks. None of the correlations were significant, but there was an indication that the variation in wingbeat frequency was negatively correlated with the residual wing loading (figure 4) (Pearson's correlation: $\rho = -0.445$, $R^2 = 0.131$, p -value = 0.111).

3.3. Do birds adjust different kinematic parameters to vary speed and climb rate?

Climb rate had a positive effect on the relationship between wingbeat frequency and amplitude in tropicbirds, demonstrating that birds increased their wingbeat amplitude to a greater extent in climbing flight (table 3). The same effect was seen in barn owls, although the R^2 was low. We were

Figure 4. Variation in wingbeat frequency as a function of morphological parameters for 14 species: (a) body mass, (b) residual wing loading (where positive values indicate species with higher wing loading than expected for a given mass) and (c) wingspan. Birds with similar flights style are marked with the same colour: red represents specialist soaring fliers, green represents obligate flapping fliers and the blue indicates birds that use mix of flapping and soaring.

Table 2. The relationship between heave amplitude and wingbeat frequency for 14 species flying in the wild and two species flying in controlled conditions.

^aWind tunnel studies.

not able to make any meaningful conclusion concerning pigeons flying in the wild as the fixed effects in the model explained only 1% of the variance in the response variable ($R_m^2 = 0.01$; table 3).

Airspeed did not affect the relationship between wingbeat frequency and amplitude in tropicbirds ($p = 0.164$), barn owls ($p = 0.546$), or in pigeons, where the model explained only 3% of the variability in the response variable ($R_m^2 = 0.03$; see electronic supplementary material, table S2). By contrast, there was a clear increase in heave amplitude with airspeed for a pigeon flying in the wind tunnel (figure 5).

We found 22 studies where the relationship between wingbeat frequency, wingbeat amplitude and either mechanical

power, speed or climb rate was quantified (table 4). Of these, 10 were performed with Passeriformes. Kinematic analyses were mostly conducted using high-speed cameras to quantify wingbeat frequency and amplitude for birds either flying in wind tunnels or flight chambers.

Wingbeat frequency had a U-shaped relationship with speed (to a variable degree) in the following species: pigeon, barn swallow, thrush nightingale, zebra finch, budgerigar and Eurasian teal. However, two further studies with thrush nightingale and cockatiel found no/different relationships between wingbeat frequency and speed, and another three studies found no relationship between wingbeat frequency and speed in black-legged kittiwake, common swift and a rufous hummingbird (table 4). One

Figure 5. (a) Wingbeat frequency and (b) signal amplitude for a pigeon flying in a wind tunnel at a range of airspeeds. Each data point is an average of five consecutive wingbeats. Periods of consistent flight were selected for analysis.

Table 3. Models of heave amplitude as a function of wingbeat frequency (WBF) and the interaction between wingbeat frequency and climb rate (V_z) for red-tailed tropicbirds ($n = 10$), pigeons ($n = 9$) and barn owls ($n = 10$), using individual as a random factor.

study found a U-shaped relationship between wingbeat amplitude and speed, and three others found a notable positive relationship (in pigeons, kittiwake and common swift) (table 4). The two studies on pigeons found that wingbeat amplitude varied in ascending and descending flights. Information on wingbeat amplitude was available for the budgerigars and it did not vary significantly with speed. Four studies on hummingbirds showed that wingbeat amplitude increased with power during hovering.

Results from a further seven studies showed that the relationships between metabolic power and wingbeat frequency and amplitude were similarly variable (table 5). While wingbeat frequency was positively correlated with the metabolic power in four studies, either it did not vary significantly or stayed constant in two studies, and it declined in one study. Furthermore, cockatiels in two different studies exhibited a discrepancy between the wingbeat frequency and the power variation for the same speed range and flight mode: while the power had a U-shaped relationship with speed, wingbeat frequency varied in the same fashion

in one case but was negatively related to speed in another. Out of three studies reported, wingbeat amplitude was closely correlated with power in two.

4. Discussion

The total power output of a bird in flapping flight varies between level, accelerating, ascending/descending, manoeuvring and load carrying flight, as well as with flight speed. Birds are expected to modulate the power output predominantly through wingbeat frequency and/or wingbeat amplitude changes, as first principles state that power output is directly proportional to the cube of the product of wingbeat frequency and amplitude. Metrics from onboard accelerometers should be able to provide insight into the relative importance of both these parameters. Our data from wind tunnel flights confirm this, by showing that the amplitude of the dorsoventral body acceleration (heave) and the wingbeat amplitude are positively related within a wingbeat cycle. While the R^2 values varied substantially between the two pigeons (0.08 versus 0.24; figure 3), this is unlikely to reflect differences in kinematics, which should be consistent across individuals for the same flight style; instead, the variance in these relationships is likely to have been affected by the flight consistency, and possibly the stability of the magnet attachment. More broadly, the ability to resolve relative changes in wingbeat amplitude from the acceleration signal may show some variation with flight style; for instance, peaks associated with wingbeats can be harder to resolve against a baseline that varies due to centripetal acceleration, as occurs throughout the dynamic soaring cycle. This may help explain the lack of a correlation between wingbeat frequency and acceleration amplitude in three of the four species that used dynamic soaring in this study, although this could also reflect a genuine absence of a relationship in this group.

The question that follows is, to what extent do birds modify wingbeat frequency and/or amplitude to modulate power output? We found that wingbeat frequency and amplitude were correlated for pigeons, and wingbeat amplitude increased with increasing flight speed (similar to another pigeon study [6]). It was, therefore, surprising that we found no relationship between wingbeat frequency, amplitude and airspeed in pigeons during homing flights. The discrepancy between our wind tunnel and 'wild' flights

Table 4. Summary of studies assessing the relationship between wingbeat frequency, amplitude and mechanical power output.

species	method	flight mode	speed (m s ⁻¹)	remarks	source
pigeon <i>Columba livia</i>	field data—GPS and accelerometer measurements	level, ascending and descending flight, all while circling	10–18	as speed increased WBF—varied approx. U shaped WBA—increased at constant speed, as power increased WBF—increased WBA—decreased ascending flight WBF—increased WBA—increased accelerating flight WBF—increased WBA—increased	Usherwood <i>et al.</i> [6]
pigeon <i>Columba livia</i>	platform—muscle force measurements and kinematic analysis with high-speed cameras	ascending, level and descending	1.4–3.9	in different flight modes WBF—did not vary significantly WBA—decreased during take-off and prior to landing	Tobalske & Biewener [30]
common starling <i>Sturnus vulgaris</i>	wind tunnel—respirometry masks and kinematics analysis with high-speed cameras	level flight	6–14	as speed increased WBF—increased (less significant) WBA—increased (less significant) power—increased	Ward <i>et al.</i> [27]
Eurasian tree sparrow <i>Passer montanus</i>	experiments in flight chamber—kinematics analysis with high-speed cameras	vertical flight	—	as maximum load lifted WBF—no significant variation WBF—no significant variation	Wang <i>et al.</i> [32]
barn swallow <i>Hirundo rustica</i>	wind tunnel—energetic costs measured by DLW, and kinematics analysis is by video recordings	level flight	8–11.5	as speed increased WBF—varied as U shaped as mass increased WBF—increased power—increased	Schmidt-Wellenburg <i>et al.</i> [23]
blue tit <i>Cyanistes caeruleus</i>	flight inside a custom-built box—kinematics analysis with high-speed cameras	take-off	3.4	as wing loading increased WBF—decreased WBA—did not vary power—decreased AR—increased	McFarlane <i>et al.</i> [58]
thrush nightingale <i>Luscinia luscinia</i>	wind tunnel—PIV and kinematics analysis with high-speed cameras	level flight	5–10	as speed increased WBF—no significant variation WBA—no significant variation	Rosén <i>et al.</i> [25]
thrush nightingale <i>Luscinia luscinia</i>	wind tunnel—wingbeat frequency measured using a shutter stroboscope and video recording	level flight	5–16	as mass increased WBF—increased as speed increased WBF—varied in U shape (less significantly)	Pennycuik <i>et al.</i> [22]
zebra finch <i>Taeniopygia guttata</i>	wind tunnel—kinematics analysis with high-speed cameras	intermittent flap-bounding flight	0–14	as speed increased WBF—increased (less significant) WBA—decreased (significantly)	Tobalske <i>et al.</i> [59]
zebra finch <i>Taeniopygia guttata</i>	surgical procedures to measure flight muscle activity	?	—	as power increased WBF—no significant effect WBA—increased effectively	Bahlman <i>et al.</i> [60]
zebra finch <i>Taeniopygia guttata</i>	wind tunnel—muscle <i>in vivo</i> pectoralis fascicle strain measurements, and kinematics by high-speed video recordings	level flight	0–14	as speed increased WBF—varied approx. U shaped WBA—increased only at hovering	Ellerby & Askew [20]

species	method	flight mode	speed (m s ⁻¹)	remarks	source
budgerigar <i>Melopsittacus undulates</i>	wind tunnel—muscle <i>in vivo</i> pectoralis fascicle strain measurements, and kinematics by high-speed video recordings	level flight	4–16	as speed increased WBF—varied approx. U shaped WBA—did not vary significantly	Ellerby & Askew [20]
cockatiel <i>Nymphicus hollandicus</i>	wind tunnel— <i>in vivo</i> pectoralis muscle length change measurements	level flight	0–16	as speed increased power—increased (approx. U shaped) WBF—reduced (highest at the lower range)	Morris & Askew [61]
cockatiel <i>Nymphicus hollandicus</i>	wind tunnel— <i>in vivo</i> surgical procedures and kinematics analysis with high-speed cameras	level flight	0–14	as speed increased WBF—reduced at lower speed and increased at higher speed (approx. U shaped) power—varied (approx. U shaped)	Hedrick <i>et al.</i> [21]; Tobalske <i>et al.</i> [19]
Eurasian teal <i>Anas crecca</i>	wind tunnel—wingbeat frequency measured using a shutter stroboscope and video recording	level flight	5–16	as mass increased WBF—increased as speed increased WBF—varied in U shape (less significantly)	Pennycook <i>et al.</i> [22]
black-legged kittiwake <i>Rissa tridactyla</i>	wild study—kinematics and airspeed data of commuting flights measured using GPS and accelerometer devices	flap–glide flight (predominantly flapping)	2–16	as speed increased WBF—no significant relationship WBA—increased significantly (as proxy by body moving amplitude)	Collins <i>et al.</i> [62]
Harris's hawk <i>Parabuteo unicinctus</i>	outdoor flight—accelerometry data and kinematic analysis using video recordings	climbing flight	—	as climb power increased WBF—increased linearly with lesser variation WBA—increased linearly with higher variation (as proxy by body moving amplitude)	Van Walsum <i>et al.</i> [13]
common swift <i>Apus apus</i>	wind tunnel—PIV and kinematics analysis with high-speed cameras	level flight	8–9.2	as speed increased WBF—decreased WBA—increased	Henningson <i>et al.</i> [63]
ruby-throated hummingbird <i>Archilochus colubris</i>	flight experiments in an airtight cube—varying air density treated with heliox	hovering	—	as power increased WBF—increased (less significant) WBA—increased (significantly) as air density decreased power—increased	Chai & Dudley [64]
ruby-throated hummingbird <i>Archilochus colubris</i>	flight experiments in an airtight cube—varying air density treated with helium	hovering	—	as power increased WBF—did not vary WBA—increased (significantly) as air density decreased power—increased	Chai & Dudley [65]
ruby-throated hummingbird <i>Archilochus colubris</i>	cubic testing arena—surgical procedures to measure flight muscle activity and kinematics analysis with high-speed cameras	hovering	—	as load lifted increased WBF—did not vary WBA—increased (significantly) as air density decreased WBF—did not vary WBA—increased (significantly)	Mahalingam & Welch [66]
rufous hummingbird <i>Selasphorus rufus</i>	wind tunnel—kinematics analysis with high-speed cameras	hovering and level flight	0–12	as speed increased WBF—did not vary WBA—increased (approx. U shaped)	Tobalske <i>et al.</i> [67]

Table 5. Summary of studies assessing the relationship between wingbeat frequency, amplitude and metabolic power.

species	method	flight mode	speed (m s ⁻¹)	remarks	source
common starling <i>Sturnus vulgaris</i>	wind tunnel—measurements of oxygen consumption and carbon dioxide production, and kinematics analysis recorded on magnetic tape	burst flapping and gliding	6–18	as power stayed almost constant WBF—constant WBA—varied approx. U shaped	Torre-Bueno & Larochelle [31]
black-billed magpie <i>Pica hudsonia</i>	wind tunnel—pectoralis muscle force based on bone-strain recordings and muscle fibre length	hovering and level flight	0–14	as power varied L shaped WBF—varied U shaped	Dial <i>et al.</i> [68]
cockatiel <i>Nymphicus hollandicus</i>	wind tunnel—measurements of oxygen consumption and carbon dioxide production	level flight	6–14	as speed varied as U shaped WBF—varied approx. U shaped WBA—varied approx. U shaped	Morris <i>et al.</i> [69]
cockatiels <i>Nymphicus hollandicus</i>	wind tunnel—measurement of oxygen consumption using masks	level flight	5–15	as power varied as U shaped WBF— decreased significantly	Bundle <i>et al.</i> [70]
budgerigars <i>Melopsittacus undulatus</i>	wind tunnel—measurement of oxygen consumption using masks	level flight	5–15	as power varied as U shaped WBF—did not vary significantly	Bundle <i>et al.</i> [70]
budgerigars <i>Melopsittacus undulatus</i>	wind tunnel—measurements of oxygen consumption and carbon dioxide production	ascending, level and descending flight	5–13	as power varied as U shaped WBF—constant	Tucker [71]
bar-headed goose <i>Anser indicus</i>	migratory flight—measurements using data loggers	ascending, level and descending flight	—	power increased as WBF ^{6.96} WBA increased with power	Bishop <i>et al.</i> [8]

may be related to the extremely variable nature of pigeon homing flights when flying solo [3]. Indeed, the substantial (and costly) variation in speed and rate of change in altitude has been proposed to serve as a predator avoidance strategy, which birds such as pigeons may adopt when flocking is not possible [3]. This is relevant in the current context as it could mask a relationship between wingbeat frequency, amplitude and airspeed in homing flights. This highlights that birds experience very different biological and physical

environments when flying in the laboratory and in the wild, which can in turn affect their kinematics. There are also likely to be errors in the estimation of airspeed, as wind conditions were recorded near the release site and while this was within 5.7 km of the loft, the wind field will be affected by the local topography as well as flight altitude. These errors will be larger for the tropicbird study, where GPS locations were recorded once a minute and wind speeds were measured up to tens of kilometres away from

the bird locations, which likely contributes to the lack of a correlation between kinematic parameters and airspeed in this species. Nonetheless, the positive relationship between kinematic parameters and climb rates for tropicbirds shows that relationships can be resolved using high-frequency data from birds flying in the wild as, unlike wind, pressure was recorded with sub-second resolution.

Our finding that wingbeat frequency and amplitude were positively correlated in 11 of the 14 species that we investigated suggests that both parameters tend to be involved in power modulation across a range of morphologies and body masses. However, the low R^2 values indicate that they are unlikely to covary in a straightforward manner, as also indicated by the variable relationship between wingbeat frequency and amplitude in other studies: five studies reported a positive correlation, five reported a negative relationship and three reported no correlation (table 2). Nonetheless, our review of the literature did suggest that birds tend to increase their wingbeat amplitude more in the most energetically demanding forms of flight (table 4), consistent with our finding that tropicbirds increased their wingbeat amplitude to a greater extent than frequency when climbing. For instance, while Usherwood *et al.* [6] found that wingbeat frequency increased during all flight modes for pigeons flying in a flock, the wingbeat amplitude increased with induced power, climb rate, and accelerating flight. Parallels can be found in studies by Tobalske & Biewener [30], where pigeons varied their wingbeat amplitude, but not frequency, during take-off and landing. Zebra finches (*Taeniopygia guttata*) were also found to modulate wingbeat amplitude rather than wingbeat frequency for high power events [20,60], but not in level flight [20]. Other studies have shown that wingbeat amplitude increased to meet the power demand associated with load carrying in hovering/vertical flight, whereas the wingbeat frequency remained near constant [66]. Similarly, hummingbirds increased their wingbeat amplitude when flying in low-density air, both in the laboratory [64–66] and in the field along natural elevational gradients [72,73], with wingbeat amplitudes up to 180° at flight failure densities.

Yet flight mode alone does not explain which kinematic parameter birds select to modulate their flight power, as while we found 10 studies where wingbeat frequency increased with airspeed in non-hovering flight, there were negative relationships between frequency and airspeed in two studies, and no relationship in 10 studies (table 4) including our ‘wild’ data. The variation across studies is striking and extends beyond comparisons between laboratory and field settings. In fact, differing relationships were found within two species (cockatiels and thrush nightingales) in experimental studies, which may indicate the influence of factors such as turbulence levels in wind tunnels, or the difficulties of training birds to maintain steady level flight, both of which could have a notable impact on the variability of kinematic parameters over fine scales.

We found limited support for the hypothesis that morphology influences variation in kinematic parameters, although birds with high residual wing loading, such as auks, did appear to have relatively low variation in wingbeat frequency, consistent with their relatively low available power. It would be interesting to see whether this non-significant negative correlation persists if data from a greater number of species were included.

This study has focused on variation in wingbeat frequency and amplitude. However, birds can also vary the aerodynamic forces through changes in the other wingbeat kinematic parameters and wing flexing and it is unclear whether and how they could all be captured by body-mounted accelerometers. Other kinematics parameters that have a significant role in power output include the upstroke-to-downstroke ratio, stroke-plane angle, span ratio, twist and angle of attack. In experiments with a house martin (*Delichon urbicum*) and a thrush nightingale (*Luscinia luscinia*), the upstroke-to-downstroke ratio and span ratio varied with increasing flight speed, whereas the wingbeat frequency and amplitude did not [25,26]. Similarly, Ward *et al.* [27] showed that for a common starling (*Sturnus vulgaris*), the wingbeat frequency and amplitude were the least important parameters associated with an increase in power, compared to variations in the stroke-plane angle and downstroke ratio. Finally, several species vary the body angle and stroke-plane angle to support weight at low speeds and augment thrust at higher speeds, while frequency and amplitude varied to a lesser degree in these scenarios [74]. The situation is potentially even more complex in intermittent flap-bounding flight, and indeed, cycle time spent flapping, flapping-and-bounding duration and the number of flaps were more important than wingbeat frequency and amplitude for a zebra finch increasing its flight speed [59].

Overall, in terms of the implications for acceleration metrics to act as proxies for flight power, it is clear that body-mounted accelerometers can provide information on wingbeat amplitude as well as frequency, both of which show substantial variation when considered across free-ranging flights in multiple species. Acceleration metrics that incorporate variation due to wingbeat frequency and amplitude, such as DBA and body power [34,36] should, therefore, be more robust proxies for power use than wingbeat frequency alone. In support of this, DBA has been shown to be a better predictor of overall energy expenditure (estimated with doubly labelled water) than flight time or wingbeat frequency in auks [35,75]. Nonetheless, wingbeat frequency and amplitude are only partial determinants of the wingbeat kinematics associated with power, and other factors play a substantial role in power production for certain flight types [76]. Some of these, e.g. the downstroke ratio, may be estimated from onboard accelerometers [14], although the magnetometer is a valuable addition in this regard, highlighting when the downstroke begins and ends (e.g. figure 2). Beyond this, what is clear is that while relationships between DBA and energy expenditure are linear for terrestrial and aquatic forms of locomotion (a relationship that holds across tens of species and over different timeframes [33,77,78]), it is unlikely to be the case for all types of flight, not least because of the varying contribution of wingbeat frequency and amplitude to power. Experiments with independent estimates of power output will provide further insight into the performance of acceleration-based proxies and the extent to which single metrics applied across species and contexts.

Ethics. We have included the details of ethical approval for each species in the electronic supplementary material [79].

Data accessibility. Additional data are available in the electronic supplementary material [79].

Conflict of interest declaration. We declare we have no competing interests.

Funding. This work was supported by European Research Council starter grant no. 715874 to E.L.C.S., under the European Union's Horizon 2020 research and innovation programme. Rory Wilson supplied the tags that were used for data collection in the studies on imperial cormorants, wandering albatrosses, grey-headed albatrosses and streaked shearwaters. Fieldwork on northern fulmars was supported by the BlueFish project, funded by the European Regional

Development fund through the Ireland Wales Co-operation Programme (2014–2020) and an extended field team. Fieldwork on northern gannets was supported by the FishKOSM project funded by the Department of Agriculture Food and the Marine (15/S/744). The wind tunnel experiments at Lund University were supported by the Swedish Research Council (2016-03625) and A.H. Linus Hedh helped training the dunlin for wind tunnel flight. Data collection in the Max Planck wind tunnel was supported by a Max Planck Sabbatical Fellowship (to E.L.C.S.). Fieldwork on black-legged kittiwakes was assisted by the Middleton Island Field Crew of 2019. Funding for Brünnich's guillemot and black-legged kittiwake work was partially from the Natural Sciences and Engineering Research Council of Canada (to K.H.E.). Fieldwork on the barn owls was funded by Swiss National Science Foundation (310030, 200321 to A.R.). We thank the National Parks and Conservation Service, the Government of Mauritius, for permission to conduct the fieldwork on the red-tailed tropicbirds and the Round Island Wardens for their support in the field. Research in Japan was funded by Grants-in-Aid for Scientific Research from the Japan Society of the Promotion of Science (16K21735, 16H06541, 21H05294 to K.Y.). We also thank Gil Bohrer for essential help in setting up the sonic anemometer for in-flight measurements of air movement.
