BRITISH GEOLOGICAL SURVEY

The full range of our publications is available from BGS shops at Nottingham, Edinburgh, London and Cardiff (Welsh publications only) see contact details below or shop online at www.geologyshop.com

The London Information Office also maintains a reference collection of BGS publications, including maps, for consultation.

We publish an annual catalogue of our maps and other publications; this catalogue is available online or from any of the BGS shops.

The British Geological Survey carries out the geological survey of Great Britain and Northern Ireland (the latter as an agency service for the government of Northern Ireland), and of the surrounding continental shelf, as well as basic research projects. It also undertakes programmes of technical aid in geology in developing countries.

The British Geological Survey is a component body of UK Research and Innovation.

Glossary

BGS	British Geological Survey: An organisation providing expert advice in all areas of geoscience to the UK government and internationally
DMD	Disaster Management Department: Prime Minister's Office of Tanzania focused on disaster risk
DRM	Disaster Risk Management; the application of disaster risk reduction policies and/or strategies
DS	Damage State
EDP	Engineering Demand Parameters
EO	Earth Observation; the gathering of information about Earth's physical, chemical and biological systems via remote sensing technologies, usually involving satellites carrying imaging devices
FATHOM	Provides innovative flood modelling and analytics, based on extensive flood risk research
GCRF	Global Challenges Research Fund
GEM	Global Earthquake Model: Non-profit organisation focused on the pursuit of earthquake resilience worldwide
HOT	Humanitarian OpenStreetMap Team: A global non-profit organisation the uses collaborative technology to create OSM maps for areas affected by disasters
ImageCat	International risk management innovation company supporting the global risk and catastrophe management needs of the insurance industry, governments and NGOs
IPP	International Partnership Programme; the UK Space Agency's International Partnership Programme (IPP) is a £30M per year programme, which uses expertise in space-based solutions, applications and capability to provide a sustainable economic or societal benefit to emerging nations and developing economies
IM	Intensity Measure
LDC	Least Developed Country on the Organisation for Economic Co-operation and Development's (OECD) Development Assistance Committee (DAC) list
M	Milestone, related to work package deliverable
METEOR	Modelling Exposure Through Earth Observation Routines; a three-year project funded by the UK Space Agency to develop innovative application of Earth Observation (EO) technologies to improve understanding of exposure and multihazards impact with a specific focus on the countries of Nepal and Tanzania
NGO	Non-Governmental Organisation; organisations which are independent of government involvement

NSET	National Society for Earthquake Technology: Non-governmental organisation working on reducing earthquake risk in Nepal and abroad
ODA	Official Development Assistance; government aid that promotes and specifically targets the economic development and welfare of developing countries
OPM	Oxford Policy Management: Organisation focused on sustainable project design and implementation for reducing social and economic disadvantage in low-income countries
PDC	Pyroclastic Density Current
PGA	Peak Ground Acceleration
SDGs	Sustainable Development Goals; these goals were set up in 2015 by the United Nations General Assembly and are intended to be achieved by the year 2030
SDOF	Single Degree Of Freedom
SRSS	Square Root of the Sum of the Squares
UKSA	United Kingdom Space Agency; an executive agency of the Government of the United Kingdom, responsible for the United Kingdom's civil space programme
WP	Work Package; discrete sets of activities within the METEOR Project, each work package is led by a different partner and has specific objectives

Foreword

This report is the published product of a study by the Global Earthquake Model Foundation (GEM) as part of the Modelling Exposure Through Earth Observation Routines (METEOR) project led by British Geological Survey (BGS).

METEOR is grant-funded by the UK Space Agency's International Partnership Programme (IPP), a >£150 million programme which is committed to using the UK's space sector research and innovation strengths to deliver sustainable economic, societal, and environmental benefit to those living in emerging and developing economies. IPP is funded from the Department for Business, Energy and Industrial Strategy's (BEIS) Global Challenges Research Fund (GCRF). This £1.5 billion Official Development Assistance (ODA) fund supports cutting-edge research and innovation on global issues affecting developing countries. ODA-funded activity focuses on outcomes that promote long-term sustainable development and growth in countries on the OECD Development Assistance Committee (DAC) list. IPP is ODA compliant, being delivered in alignment with UK Aid Strategy and the United Nations' (UN) Sustainable Development Goals (SDGs).

Summary

This report describes a specific piece of work conducted by Global Earthquake Model Foundation (GEM) as part of the METEOR (Modelling Exposure Through Earth Observation Routines) project, led by British Geological Survey (BGS) with collaborative partners Oxford Policy Management Limited (OPM), SSBN Limited, The Disaster Management Department, Office of the Prime Minister – Tanzania (DMD), The Global Earthquake Model Foundation (GEM), The Humanitarian OpenStreetMap Team (HOT), ImageCat and the National Society for Earthquake Technology (NSET) – Nepal.

The 3-year project was funded by UK Space Agency through their International Partnership Programme, details of which can be located in the Foreword, and was completed in 2021.

The project aimed to provide an innovative solution to disaster risk reduction, through development of an innovative methodology of creating exposure data from Earth Observation (EO) imagery to identify development patterns throughout a country and provide detailed information when combined with population information. Level 1 exposure was developed for all 47 least developed countries on the OECD DAC list, referred to as ODA least-developed countries in the METEOR documentation, with open access to data and protocols for their development. New national detailed exposure and hazard datasets were also generated for the focus countries of Nepal and Tanzania and the impact of multiple hazards assessed for the countries. Training on product development and potential use for Disaster Risk Reduction was performed within these countries with all data made openly available on data platforms for wider use both within country and worldwide.

This report (M5.3/P) is the third generated by GEM, in collaboration with NSET, for the work package on Vulnerability and Uncertainty (WP5 - led by GEM). The other 7 METEOR work packages included, Project Management (WP1 – led by BGS), Monitoring and Evaluation (WP2 – led by OPM), EO data for exposure development (WP3 – led by ImageCat), Inputs and Validation (WP4 – led by HOT), Multiple hazard impact (WP6 – led by BGS), Knowledge sharing (WP7 – led by GEM) and Sustainability and capacity building (WP8 – led by ImageCat).

1. METEOR Project

1.1. PROJECT SUMMARY

Project Title	Modelling Exposure Through Earth Observation Routines (METEOR): EO-based Exposure, Nepal and Tanzania
Starting Date	08/02/2018
Duration	36 months
Partners	UK Partners: The British Geological Survey (BGS) (Lead), Oxford Policy Management Limited (OPM), SSBN Limited International Partners: The Disaster Management Department, Office of the Prime Minister – Tanzania, The Global Earthquake Model (GEM) Foundation, The Humanitarian OpenStreetMap Team (HOT), ImageCat, National Society for Earthquake Technology (NSET) – Nepal
Target Countries	Nepal and Tanzania for “level 2” results and all 47 Least Developed ODA countries for “level 1” data
IPP Project	IPPC2_07_BGS_METEOR

Table 1: METEOR Project Summary

1.2. PROJECT OVERVIEW

At present, there is a poor understanding of population exposure in some Official Development Assistance (ODA) countries, which causes major challenges when making Disaster Risk Management decisions. Modelling Exposure Through Earth Observation Routines (METEOR) takes a step-change in the application of Earth Observation exposure data by developing and delivering more accurate levels of population exposure to natural hazards. METEOR is delivering calibrated exposure data for Nepal and Tanzania, plus ‘Level-1’ exposure for the remaining Least developed Countries (LDCs) ODA countries. Moreover, we are: (i) developing and delivering national hazard footprints for Nepal and Tanzania; (ii) producing new vulnerability data for the impacts of hazards on exposure; and (iii) characterising how multi-hazards interact and impact upon exposure. The provision of METEOR’s consistent data to governments, town planners and insurance providers will promote welfare and economic development and better enable them to respond to the hazards when they do occur.

METEOR is co-funded through the second iteration of the UK Space Agency’s (UKSA) International Partnership Programme (IPP), which uses space expertise to develop and deliver innovative solutions to real world problems across the globe. The funding helps to build sustainable development while building effective partnerships that can lead to growth opportunities for British companies.

1.3. PROJECT OBJECTIVES

METEOR aims to formulate an innovative methodology of creating exposure data through the use of EO-based imagery to identify development patterns throughout a country. Stratified sampling technique harnessing traditional land use interpretation methods modified to characterise building patterns can be combined with EO and in-field building characteristics to capture the distribution of building types. These protocols and standards will be developed for broad application to ODA countries and will be tested and validated for both Nepal and Tanzania to assure they are fit-for-purpose.

Detailed building data collected on the ground for the cities of Kathmandu (Nepal) and Dar es Salaam (Tanzania) will be used to compare and validate the EO generated exposure datasets. Objectives of the project look to: deliver exposure data for 47 of the least developed ODA countries, including Nepal and Tanzania; create hazard footprints for the specific countries;

create open protocol; to develop critical exposure information from EO data; and capacity-building of local decision makers to apply data and assess hazard exposure. The eight work packages (WP) that make up the METEOR project are outlined below in section 1.4.

1.4. WORK PACKAGES

Outlined below are the eight work packages that make up the METEOR project, which are led by various partners. Table 2 provides an overview of the work packages together with a brief description of what each of the work packages cover.

Work Package	Title	Lead	Overview
WP.1	Project Management	BGS	Project management, meetings with UKSA, quarterly reporting and the provision of feedback on project deliverables and direction across primary stakeholders.
WP.2	Monitoring and Evaluation	OPM	Monitoring and evaluation of the project and its impact, using a theory of change approach to assess whether the associated activities are leading to the desired outcome.
WP.3	EO Data for Exposure Development	ImageCat	EO-based data for exposure development, methods and protocols of segmenting/classifying building patterns for stratified sampling of building characteristics.
WP.4	Inputs and Validation	HOT	Collect exposure data in Kathmandu and Dar es Salaam to help validate and calibrate the data derived from the classification of building patterns from EO-based imagery.
WP.5	Vulnerability and Uncertainty	GEM	Investigate how assumptions, limitations, scale and accuracy of exposure data, as well as decisions in data development process lead to modelled uncertainty.
WP.6	Multiple Hazard Impact	BGS	Multiple hazard impacts on exposure and how they may be addressed in disaster risk management by a range of stakeholders.
WP.7	Knowledge Sharing	GEM	Disseminate to the wider space and development sectors through dedicated web-portals and use of the Challenge Fund open databases.
WP.8	Sustainability and Capacity-Building	ImageCat	Sustainability and capacity-building, with the launch of the databases for Nepal and Tanzania while working with in-country experts.

Table 2: Overview of METEOR Work Packages

2. Introduction to Work Package

Uncertainty is fundamental to disaster risk assessment, both from the inherent randomness of natural phenomena (e.g., depth of rainfall in a 24-hour storm) and due to our incomplete scientific knowledge of the phenomena (e.g., lack of sufficient damage data, appropriateness of a given mathematical model). These areas of uncertainty are referred to as aleatory variability and epistemic uncertainty, respectively. Lack of consideration of these sources of uncertainty in disaster risk assessment can lead to erroneous decision making. Therefore, it is essential to consider different aspects of uncertainty in the various components that compose a disaster risk assessment, and propagate those through the entire process to get a full view of the range of possible outcomes. The incorporation of all sources of uncertainty in risk assessment is a fundamental goal of the METEOR project.

This report focuses on four key areas of uncertainty related to vulnerability and exposure models. These areas include variabilities in the hazard input, building capacity, damage threshold and loss model. While this report evaluates the impact of these uncertainties on vulnerability models, a forthcoming report (M5.4) will propagate the uncertainties to both urban and regional risk assessments. Moreover, additional information about the consideration of aleatory variability and epistemic uncertainty in the hazard and exposure counterparts can be found in Winson, *et al.* (2019) and Huyck, *et al.* (2019) respectively.

3. Natural hazards vulnerability models and uncertainty

3.1. FRAGILITY AND VULNERABILITY MODELS

Fragility and vulnerability models are a fundamental component of natural hazard risk assessment. Fragility functions quantify the probability of exceeding a set of damage states (e.g. slight damage, moderate damage) for a given hazard intensity value. Those damage states can then be related to a loss ratio value or distribution. Vulnerability functions combine these two aspects to directly quantify the average damage or loss ratio for a given hazard intensity value. Generic examples of these models are shown in Figure 1.

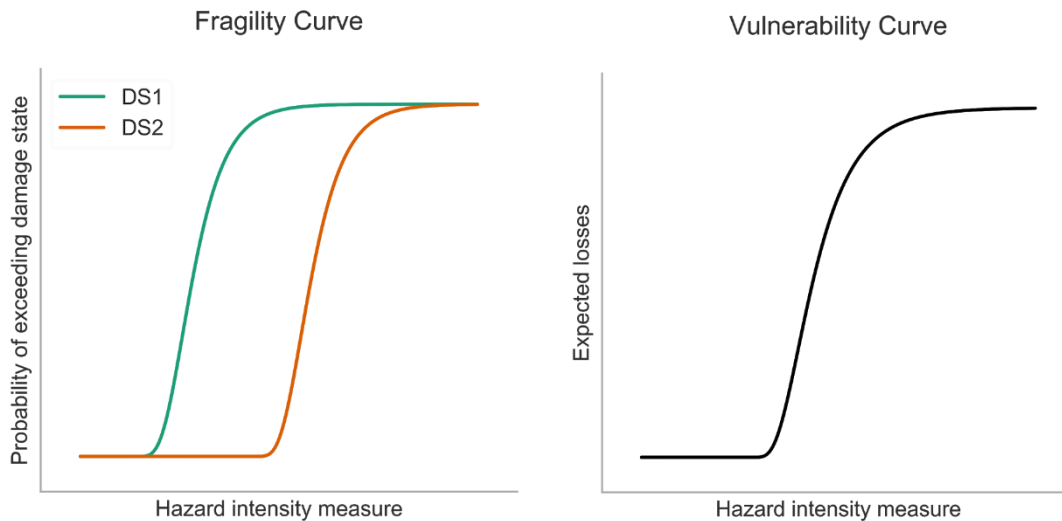

Figure 1: Graphical representation of a fragility curve for two hypothetical damage states, DS (left) and vulnerability curve (right)

Fragility and vulnerability models can be derived using empirical data, analytical methods, expert judgment, or hybrid methods. A derived fragility or vulnerability function should ideally be developed specifically for the exposure in the region of interest (e.g., considering construction materials or practices local to the area of interest). The use of empirical data is ideal, but there tends to be a lack of sufficient data, particularly for larger intensity natural hazard events that are rarer. Analytical methods can address the problem of insufficient empirical data, but entail several simplifying assumptions that require a balance between accuracy and computational space or time demands. Additionally, the complexity or number of unique fragility or vulnerability functions must be bounded by the resolution of exposure data, and/or require development of a mapping scheme to go from lower resolution exposure data to higher resolution vulnerability models.

This report explores the propagation of uncertainty in assumptions inherent to fragility or vulnerability function derivation using analytical methods. The analytical method of fragility derivation was chosen for this study because it can explicitly account for sources of uncertainty. These uncertainties are broadly categorised into hazard representation, building capacity variability, damage measure criteria definitions and loss ratio variability.

3.2. EARTHQUAKES

Vulnerability modelling of buildings for earthquake ground shaking has been a wide area of research for decades, and thus there is comparatively more published research on this topic as compared with the other considered hazards. Analytical seismic fragility and vulnerability models can be derived using either static or dynamic methods, but typically require an estimate of seismic ground shaking input (e.g. response spectra), simplification of a building into limited

dynamic response values (e.g. equivalent single degree of freedom, or SDOF, parameters) and establishment of demand-based damage criteria (e.g. drift thresholds).

As with other natural hazards, quantification of seismic hazard for the purpose of risk assessment often relies on a singular parameter or metric. The peak ground acceleration (PGA) is the most commonly used hazard metric for earthquakes. However, the spectral acceleration at the fundamental period of the structure, $S_a(T)$, has a higher correlation with damage than PGA and several other hazard metrics (Elenas, *et al.* 2001). In either case, other aspects of ground motion (e.g., duration, spectral acceleration at other periods, site soil effects) can induce varying responses in buildings, and therefore cause different levels of damage (Sousa, *et al.*, 2015; Chandramohan, *et al.*, 2016; Gehl, *et al.*, 2013). The variability of response tends to increase with increasing damage level, as the dynamic properties of the building vary with damage. For this reason, national building codes (e.g., ASCE7 in the United States¹) often prescribe a minimum number of ground motion records to be considered in the dynamic analysis of structures both for design and safety assessment.

Similarly, there are many different parameters associated with the response of a structure, often referred to as “engineering demand parameters”, or *EDPs*. The *EDP* most commonly used for earthquake response of buildings is related to the displacement, as it tends to be the most correlated with damage. However, other aspects of response can also contribute to damage (e.g., floor accelerations). Damage state thresholds similarly often use displacement-based criteria, but have an inherent randomness (e.g., buildings of a given typology could collapse at a range of different displacement values). These damage states then must be translated into losses, which have a similar variability to all the other considered hazards.

3.3. LANDSLIDES

Fragility and vulnerability functions for landslides have been published, using a range of metrics to quantify the hazard input. This is partially due to the fact that landslides can be triggered in different manners, such as from an earthquake or from heavy rainfall. Some of the used hazard metrics include peak ground acceleration, permanent ground deformation and equivalent cumulative displacement. Similar to other dynamic natural hazards, there are a variety of characteristics or mechanisms of a landslide that could result in varying damage to structures, which cannot be easily quantified as a single metric. Some of these factors include speed of the landslide, soil/rock properties and landslide geometry.

The representation of physical vulnerability of buildings to landslides typically involves an estimate of global building strength, based on construction material and quality. Although some analytical fragility or vulnerability functions for landslides exist (Fotopoulou, *et al.*, 2013; Haugen, *et al.*, 2008), expert elicitation is more commonly used to assess physical vulnerability of landslides due to an inability of some of these analytical models to successfully simulate past observations of damage (Guillard-Gonçalves, *et al.*, 2016; Singh, *et al.*, 2019). Common indicators of physical vulnerability of buildings to landslides include: height of lowest opening, foundation type, roof material, basement presence, state of maintenance, number of floors, and construction material (Dabbeek, *et al.*, 2020; Singh, *et al.*, 2019). Since there are relatively few studies that involve analytical derivation of fragility or vulnerability models, a direct assessment of uncertainty propagation for landslides is challenging. Additionally, expert elicitation methods tend to provide qualitative (as opposed to quantitative) outputs, which increases the challenge.

3.4. VOLCANOES

Fragility and vulnerability functions are less prevalent for volcanoes than for many other natural hazards, and are an area of active scientific research and development. Published functions often use tephra (ashfall) thickness or load to quantify the hazard input and simplify the building based on its roof material and pitch (Pomonis, *et al.*, 1999; Spence, *et al.*, 2008; Zuccaro, *et al.*, 2008; Jenkins, *et al.*, 2014). Tephra fall is an appealing metric for risk assessment, given it is one of the most widespread and frequent volcanic hazards, affecting large areas with impacts at

¹ Available online at: <https://www.asce.org/structural-engineering/asce-7-and-sei-standards/>

relatively low thicknesses (Blong, *et al.*, 2017; Magill, *et al.*, 2005). Although tephra thickness or load is commonly used as the metric to quantify building damage from volcanic hazards, there are many additional metrics that could result in building damage from a given scenario, including: lahar, lava flow, debris and pyroclastic density currents (Sparks, *et al.*, 2013; Wilson, *et al.*, 2014). Pyroclastic density currents (PDCs) and lava flow can produce more intense damage, but tend to only affect buildings in the immediate vicinity of the volcano.

Analytical estimations of tephra fall require assumptions around meteorological conditions (e.g., wind speed and direction, wet or dry) and ash dispersal, thereby introducing uncertainty. Some of these parameters could directly affect vulnerability models (e.g., wet versus dry tephra could result in different damage levels at the same thickness value), whereas other aspects would primarily affect the hazard quantification and therefore the risk assessment. Additionally, buildings of similar roof material and pitch can have varying strength, connection details, and geometry, thereby resulting in varying response to equivalent tephra loads. In contrast to landslides and earthquakes, analytical estimates of building damage due to tephra fall tend to be static (i.e., not dynamic), which implies less variability with respect to building response given a hazard intensity level. Similar to other discussed hazards, damage state thresholds and associated loss ratios must also be established. Roof collapse is commonly considered as the damage state, which might have varying associated loss ratios based on factors such as the building height (e.g., roof collapse of a single-story structure may be considered a complete loss, whereas a taller structure may consider it as a partial loss).

3.5. FLOODING

Several flood fragility and vulnerability functions have been published over the years (Pregolato, *et al.*, 2015) typically using flood depth to quantify the hazard input and directly relating that to a damage or loss ratio. Unlike the other considered natural hazards, derivation of flood vulnerability models tends to have less emphasis on building analysis or characteristics such as strength or dynamic properties.

Flood hazard models are reliant on a variety of data sources and types, such as digital elevations, boundary conditions, flow rates, and effective roughness parameters. Some studies have shown that even small variations in inputs like the digital elevation model can lead to large variance in the estimated inundation depths (Zerger, *et al.*, 2002). Additionally, there is inherent randomness in factors such as storm duration and rainfall depth. On top of that, estimates of these parameters are subject to a changing baseline due to climate change, which can limit the applicability of the available historic data (Kundzewicz, *et al.*, 2014).

In addition to flood depth, alternate hazard metrics such as duration, velocity, or surge can also incur damage and therefore loss to exposed buildings. Although there is likely less variance in building response to equivalent flood depths than the other, more dynamic natural hazards, there may still be some differences building to building with the existence of flood defence systems and the existence of below-grade floors or contents.

4. Case study of uncertainty in vulnerability models

4.1. METHODOLOGY

The propagation of uncertainty was performed for masonry buildings in Nepal considering earthquake ground shaking. However, the framework is generic and many takeaways equally pertain to the other natural hazards, locations and building typologies. The four broad categories of uncertainty that were considered are summarised in Table 3.

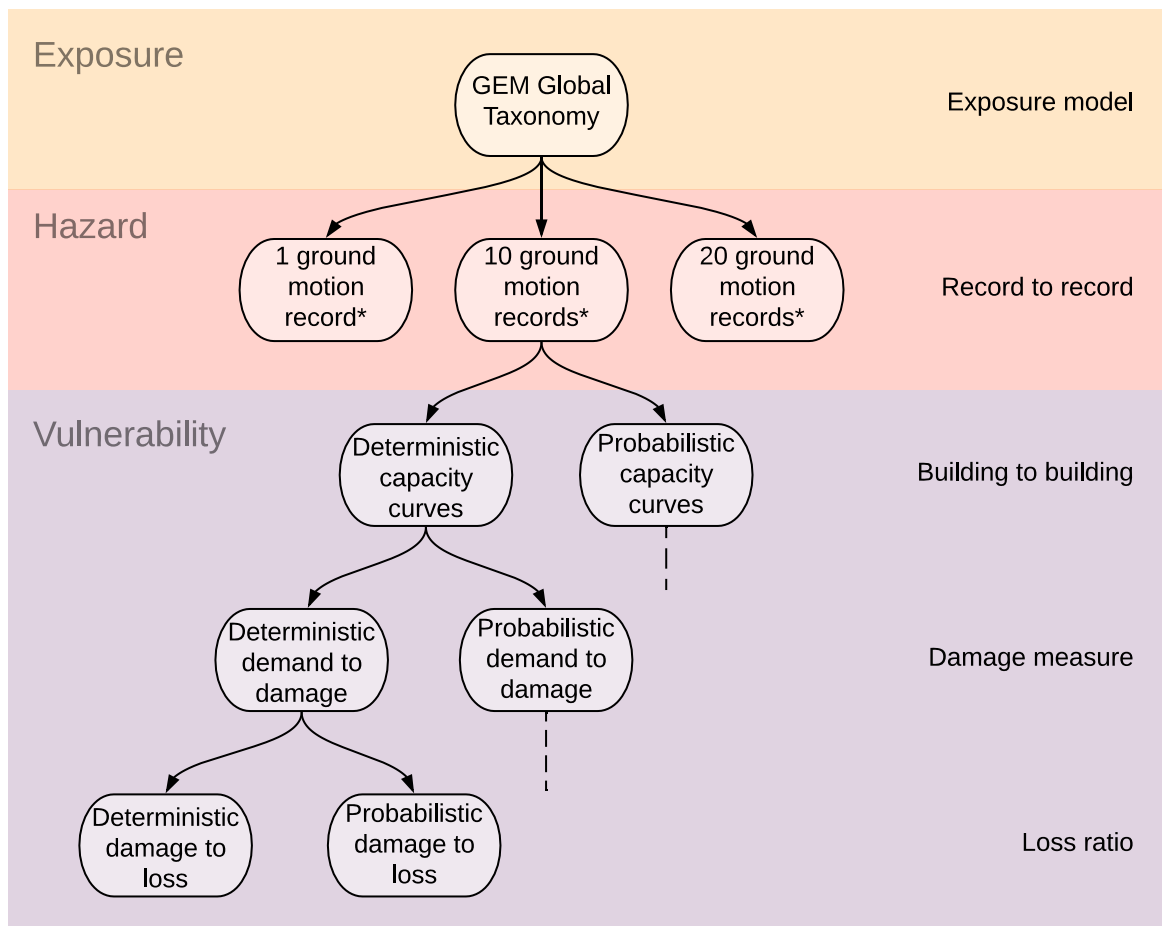

Category	Description
Hazard input	Although singular hazard metrics are often chosen for ease of computation, there are many other factors that could influence building response. This is particularly true for dynamic hazards, such as earthquakes and landslides. This area of uncertainty is explored by using different hazard inputs with equivalent values at a given intensity level, versus considering multiple hazard inputs across a range of intensity levels.
Building-to-building	Fragility or vulnerability curves require an estimate of building capacity or strength to the hazard of interest, but robust assessment of capacity typically requires more detailed information that is available in large-scale studies. However, it is not common practice to directly consider uncertainty in these estimates. Randomly sampled capacity curves were generated based on the mean capacity curves of the considered building typologies to assess this area of variability.
Damage state threshold	Fragility curves tend to differentiate between varying degrees of damage (e.g., slight, moderate, extensive, complete). However, this requires the establishment of a damage threshold, which in reality has an inherent degree of randomness. A probabilistic distribution for this parameter was considered on this threshold to assess the implications of this uncertainty.
Loss ratio	Damage states indicate a broad state of damage (e.g., slight, moderate, extensive, complete), but the proportion of loss associated with that state is inherently random. This study investigated the use of expected loss ratios at each damage state, versus modelling a Beta distribution for each damage state.

Table 3: Description of four sources of uncertainty investigated within this work package

In this report, the impact on the resulting vulnerability of each building typology was evaluated through several different manners, including:

- Distribution of resulting fragility or vulnerability models
- Distribution of average annual losses, or expected loss in a given timeframe
- Coefficient of variation of losses per intensity level

The next deliverable will instead focus on the impact of these uncertainties on disaster risk assessments at both the urban and national level. A visual representation of the logic tree to represent each of these cases is shown in Figure 2.

*Number represents target records per intensity level

Figure 2: Logic tree that describes the branches analysed to study each source of uncertainty

For this study, unreinforced masonry typologies common to Nepal were investigated. The typologies considered are summarised in Table 4, with their associated mean capacity curves shown in Figure 7.

GEM Taxonomy	Material	Lateral system	Stories
MUR/LWAL/DNO/H:1	Unreinforced masonry, unknown units*	Wall, no ductility	1
MUR/LWAL/DNO/H:2			2
MUR/LWAL/DNO/H:3			3
MUR/LWAL/DNO/HBET:4-5			4-5
MUR+ADO/LWAL/DNO/H:1	Unreinforced masonry, adobe blocks		1
MUR+ADO/LWAL/DNO/H:2			2
MUR+ST/LWAL/DNO/H:1	Unreinforced masonry, unknown stone		1
MUR+ST/LWAL/DNO/H:2			2
MUR+ST/LWAL/DNO/H:3			3

*Unknown masonry units could include any of the following types: rubble stone, fired clay (hollow or solid), concrete, stone, or adobe.

Table 4: Building typologies investigated for uncertainty propagation study

4.2. HAZARD INPUT VARIABILITY

The characterisation of natural hazards often relies on the selection of one or more intensity measures (*IM*), which reduces the complexity of the phenomena into quantifiable measures. Ideally, the selected *IM* will correlate strongly with damage or losses and is practical to estimate.

Although single *IMs* are commonly used, other characteristics of the hazard at a given intensity level may influence the degree of damage, particularly for dynamic hazards (e.g., landslides, earthquakes) once a structure has gone into the inelastic region of response (i.e. once damage initiates). This variability of response is considered as “hazard input variability” in this report, but may be referred to as other names within the hazard-specific context (e.g. “record-to-record variability” for earthquakes). Common *IMs* for each of the considered hazards are presented in Table 5, with some commentary on other metrics that could induce variability in structural response and therefore fragility or vulnerability models. An example of two potential hazard inputs with equivalent *IM* values is shown in Figure 3 for the earthquake hazard.

Hazard	Intensity measure*	Other hazard factors that contribute to damage variability
Earthquake	Peak ground acceleration, spectral acceleration at fundamental period	Spectral shape, duration of strong shaking, site-specific soil conditions, topographical conditions
Landslide	Peak ground acceleration, equivalent cumulative displacement	Mechanism of landslide, speed of landslide
Flood	Flood depth	Flood velocity, flood duration, storm surge
Volcano	Tephra thickness	Meteorological conditions

*The most commonly used intensity measures are presented for clarity

Table 5: Summary of hazard input factors that contribute to uncertainty in vulnerability estimates

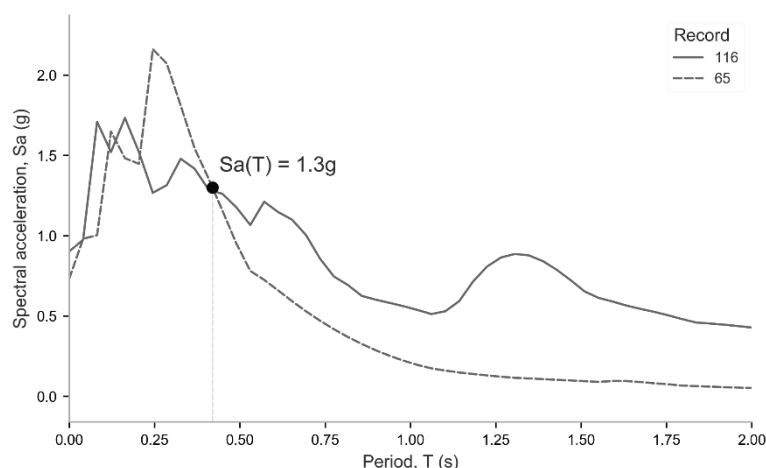

Figure 3: Comparison of two alternate ground motion records with comparable values of spectral acceleration at the period of interest ($T=0.42$)

Since earthquakes are dynamic hazards, the individual ground motion record associated with an event can have a significant influence on the behaviour of the structure and its resulting damage. Once in the inelastic region of response (i.e. once damage initiates), additional modes contribute to the behaviour of the structure, such that multiple ground motions with the same *IM*

value (e.g., $S_a(T_1)$) can lead to varying peak response values and damage. As a result, structures evaluated with relatively few ground motion records (often amplitude-scaled to cover different intensity levels) can exhibit biased nonlinear response behaviour. This is demonstrated by the varying fragility and vulnerability curves.

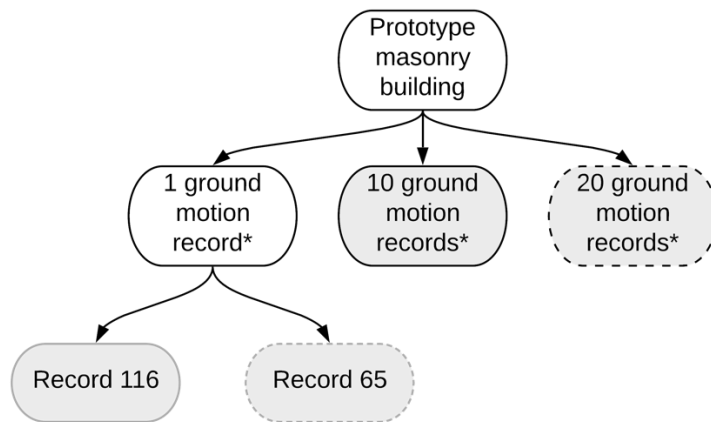

Figure 4: Logic tree describing different cases (endpoints filled in grey) studied to demonstrate hazard input variability

Figure 5: Comparison of resulting fragility curves (left) and vulnerability curves (right) from two alternate ground motion records versus 10 ground motion records per IM for building typology with $T=0.42s$, $MUR+ST/LWAL+DNO/H:3$

The resulting fragility and vulnerability curves in Figure 5 show the impact of considering multiple sets of hazard inputs at each intensity measure level. Limiting the analysis to 1 record per intensity measure level gives the illusion of increased certainty (as evidenced by the steeper slope), but the range of the distribution is biased and could sit anywhere along the range of the distribution seen using 10 records per intensity measure level. Although the consideration of 10 (versus just 1) records at each intensity level has a dramatic effect on the resulting fragility and vulnerability curves, the same degree of difference does not hold for consideration of 20 (versus just 10) records at each intensity level. This analysis is shown in Figure 6, where it can be seen that the curves with 20 records almost completely overlap with the curves with 10 records. This implies that considering 10 records per intensity level should be sufficient for fragility or vulnerability derivation.

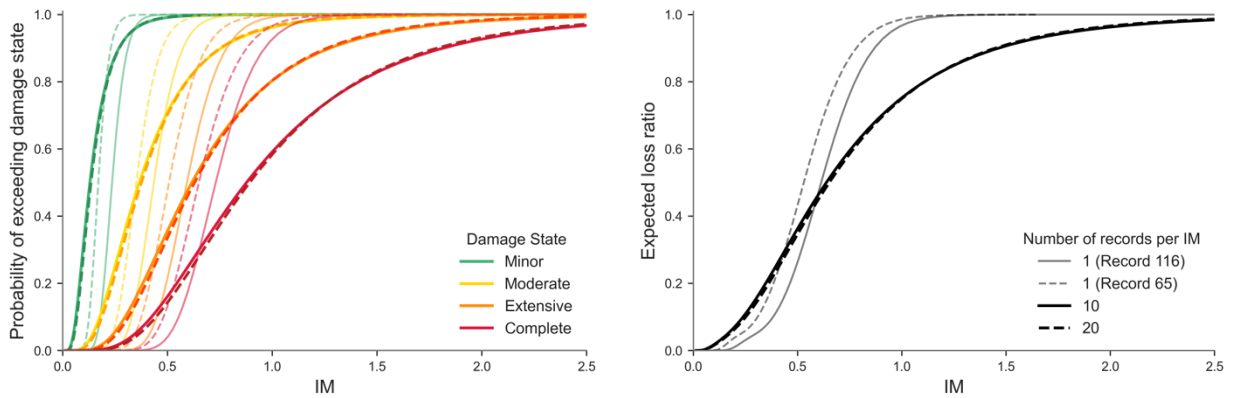

Figure 6: Comparison of resulting fragility curves (left) and vulnerability curves (right) from two alternate ground motion records versus 10 and 20 ground motion records per IM for building typology with $T=0.42s$, $MUR+ST/LWAL+DNO/H:3$

4.3. BUILDING-TO-BUILDING VARIABILITY

Disaster risk assessment typically relies on the identification of a finite number of building typologies or archetypes, which relate the exposure data to a fragility or vulnerability model. These building typologies and their associated fragility or vulnerability curves are intended to represent a group of buildings with similar features, but not intended to represent individual buildings or assets. Building or asset-specific fragility and vulnerability models would require high resolution exposure data, which typically is not available nor practically developed for large-scale studies. As such, it is anticipated there will be some variability in damage or losses due to the building-to-building variability within a given building archetype. This could be due to varying construction quality, presence of structural irregularities, or a host of other differences within the building stock. For low-strength masonry buildings, the seismic performance can be particularly sensitive to the number of stories, therefore the taxonomy used herein differentiates between building heights as seen in Figure 7 and Table 6.

Commonly, an estimate of building strength or capacity is required, usually using construction age or material type as a proxy to estimate that value. Example capacity curves estimates for the considered unreinforced masonry buildings in Nepal are shown in Figure 7 and Table 6. These refer to the 'best estimate' of capacity of these building typologies, however there is some inherent randomness as described earlier. For masonry buildings and their seismic performance, variations in wall thickness and mortar strength can be particularly influential to the seismic displacement and acceleration, respectively.

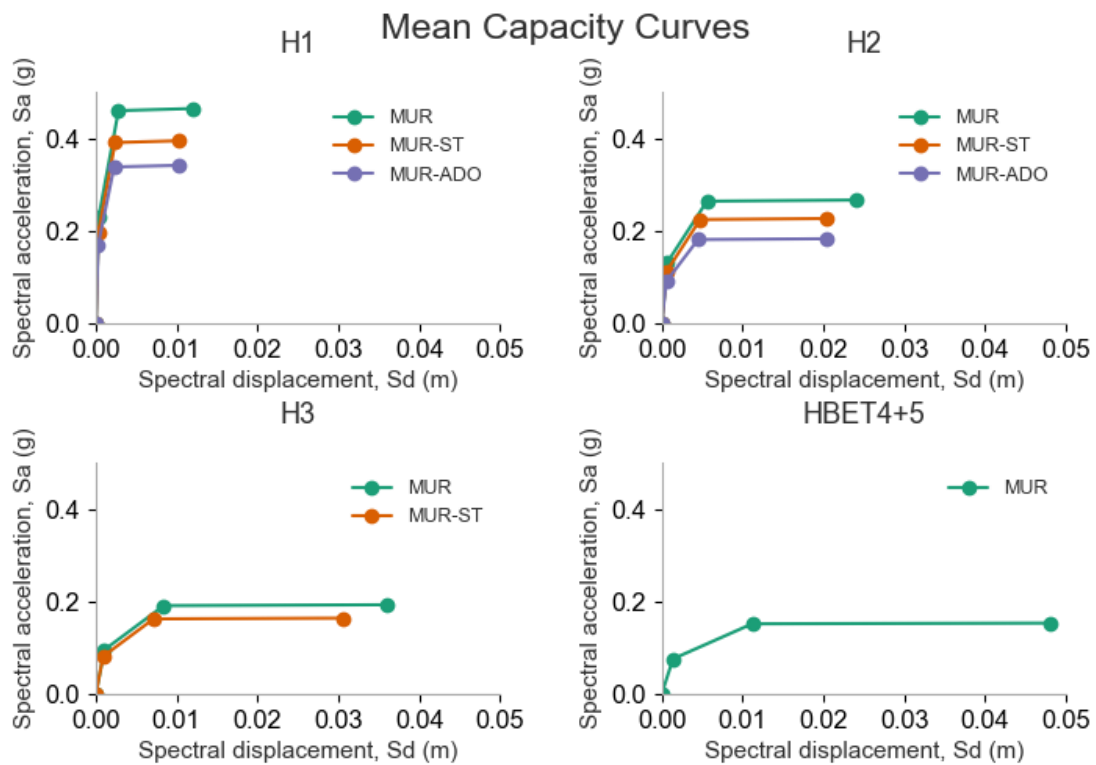

Figure 7: Mean capacity curves for considered building typologies within this case study

GEM Taxonomy	Yield period (s)	Sd,y (cm)	Sd,u (cm)
MUR/LWAL/DNO/H:1	0.16	0.04	1.2
MUR/LWAL/DNO/H:2	0.29	0.07	2.4
MUR/LWAL/DNO/H:3	0.42	0.11	3.6
MUR/LWAL/DNO/HBET:4-5	0.55	0.14	4.8
MUR+ADO/LWAL/DNO/H:1	0.16	0.03	1.0
MUR+ADO/LWAL/DNO/H:2	0.32	0.06	2.0
MUR+ST/LWAL/DNO/H:1	0.16	0.03	1.0
MUR+ST/LWAL/DNO/H:2	0.29	0.06	2.0
MUR+ST/LWAL/DNO/H:3	0.42	0.09	3.0

Table 6: Key parameters of considered building typologies within this case study

For this study, 100 statistically-consistent random samples were generated based on the mean capacity curves and run through the same analysis approach to determine the impact on vulnerability results. Figure 8 shows the distribution of 100 random samples of the capacity curves for one building typology. A multivariate lognormal distribution was assumed around

best-estimate input values for the spectral displacement at yield (initiation of damage) and at ultimate (complete failure), using a correlation of 60% and a coefficient of variation of 30% (Silva, *et al.*, 2014a; Silva, *et al.*, 2014b).

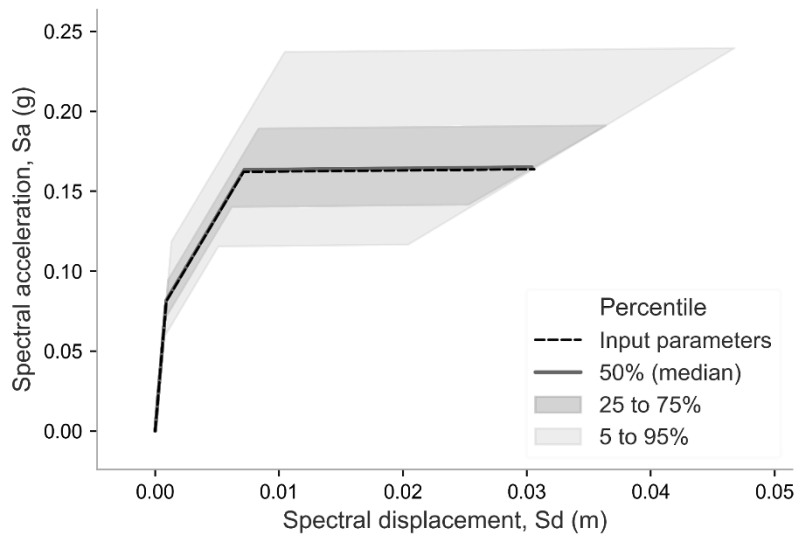

Figure 8: Comparison of resulting capacity curves from 100 random samples of MUR+ST/LWAL+DNO/H:3

The resulting distributions of fragility and vulnerability curves are shown in Figure 9 through Figure 11.

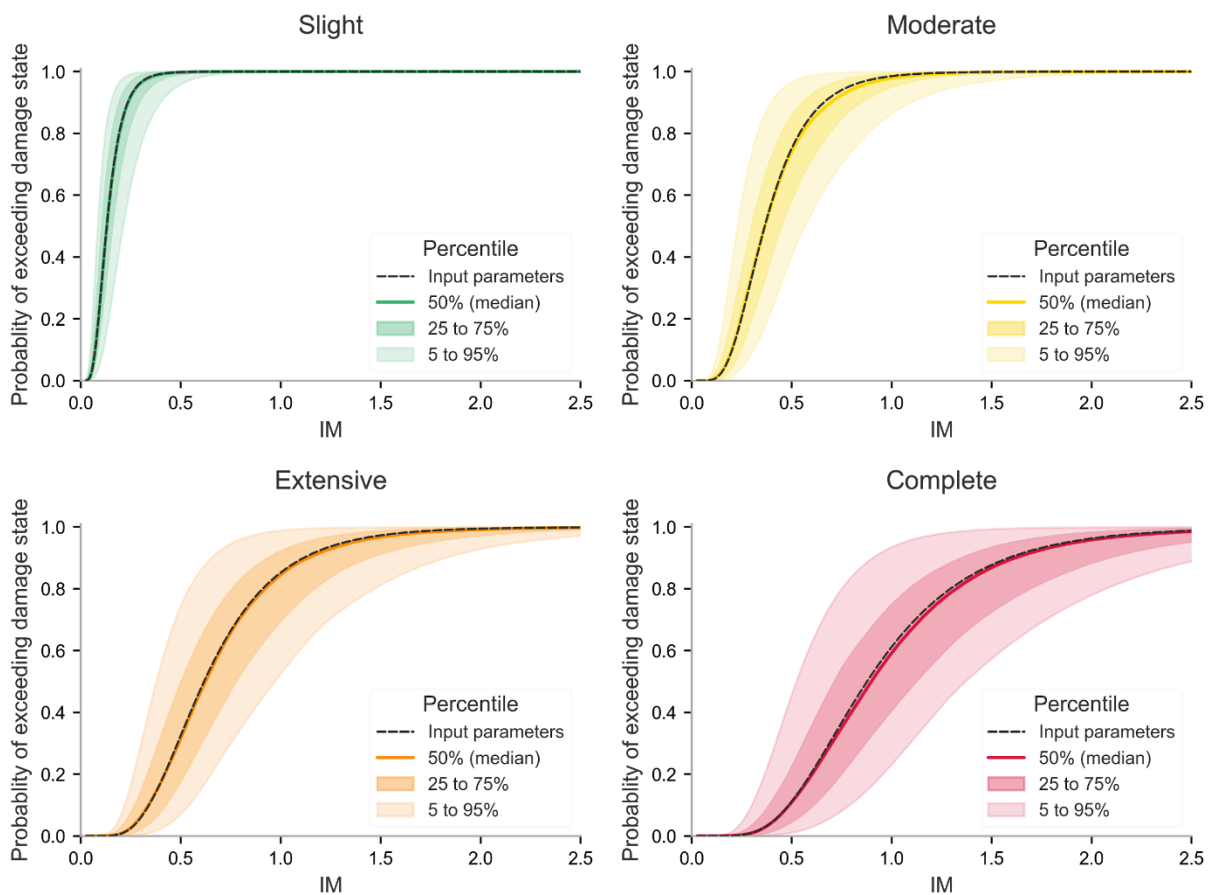

Figure 9: Comparison of resulting fragility curves from random sampling of 100 capacity curves for MUR+ST/LWAL+DNO/H:3

Figure 10: Comparison of resulting vulnerability curves from random sampling of 100 capacity curves for MUR+ST/LWAL+DNO/H:3

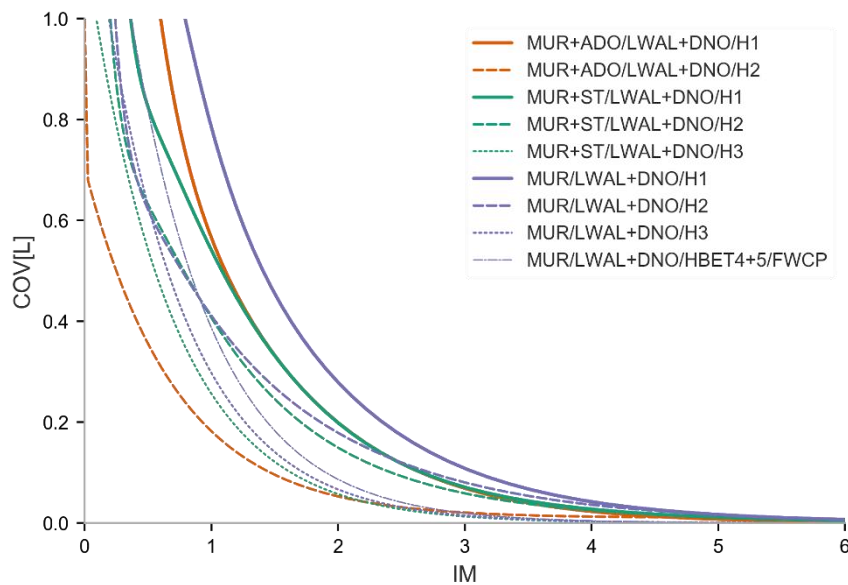

Figure 11: Coefficient of variation of losses for all considered building typologies, by intensity level

While the distribution of derived fragility and vulnerability model outcomes is significant (as evident in Figure 9 to Figure 11), the effect on the range of subsequent risk results is not necessarily as large. To investigate this, each considered building typology was convolved with the hazard curve at a representative site in Nepal to understand the implication on the average annual losses of that building typology. These losses were also converted into an expected loss in 100 years. For reference, the associated hazard curves are presented in Figure 12, which are estimated using the Stevens, *et al.* model (Stevens, *et al.*, 2018). The impact on disaster risk assessments will be considered further in the forthcoming report (METEOR M5.4).

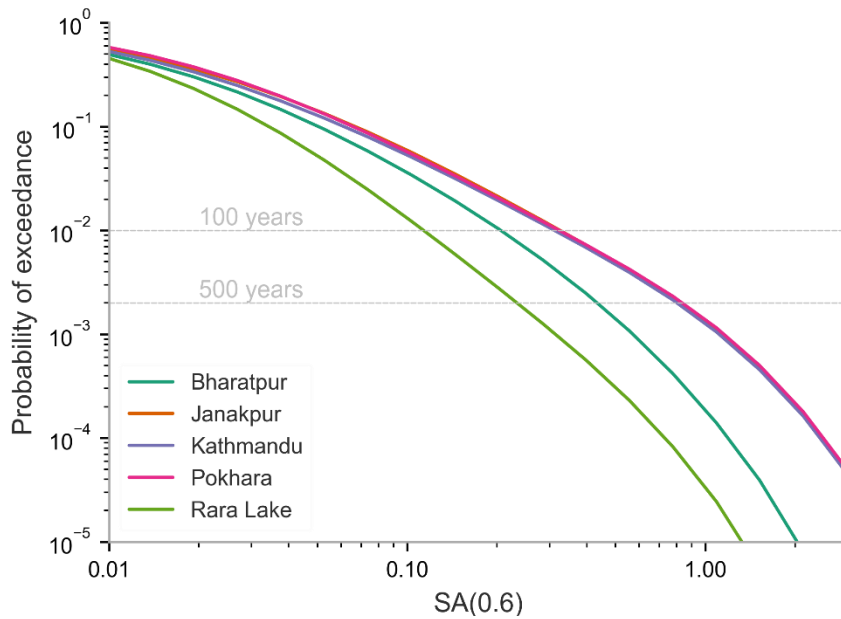

Figure 12: The hazard curves for the considered building typology's intensity measure of interest; Pokhara overlaps with Kathmandu and Janakpur. Estimated using the Stevens et. al. model (Stevens, et al., 2018).

The average annual loss values are summarised in Table 7 for an example building typology. The distribution of average annual losses is shown for all considered building typologies in Figure 13.

Location	5%ile	25%ile	50%ile	75%ile	95%ile
Bharatpur	0.14%	0.23%	0.32%	0.48%	0.74%
Janakpur	0.35%	0.53%	0.71%	0.99%	1.42%
Kathmandu	0.33%	0.49%	0.66%	0.91%	1.31%
Pokhara	0.35%	0.53%	0.70%	0.97%	1.40%
Rara Lake	0.04%	0.07%	0.11%	0.17%	0.28%

Table 7: Average annual loss values for MUR+ST/LWAL+DNO/H:3, considering varying building capacity

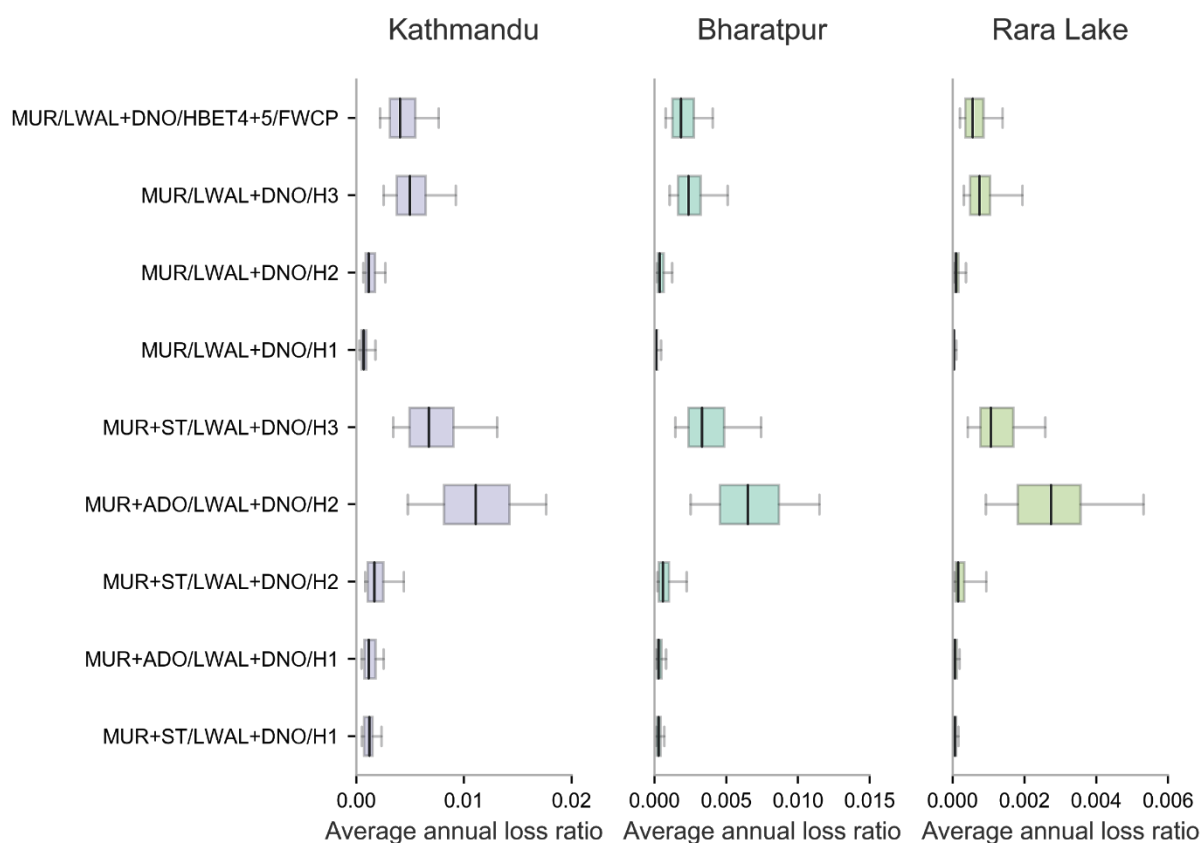

Figure 13: Comparison of percentiles (5%, 25%, 50%, 75%, and 95%) of average annual loss values for Kathmandu and Bharatpur, across all randomly sampled buildings of that typology.

The expected loss in 100 years is shown in Table 8 for all sites, and shown for different timeframes in Kathmandu in Figure 14 and Figure 15.

Location	5%ile	25%ile	50%ile	75%ile	95%ile
Bharatpur	2.9%	4.8%	6.5%	9.5%	15.0%
Janakpur	7.3%	11.2%	16.3%	25.0%	39.0%
Kathmandu	6.8%	10.2%	14.8%	22.8%	35.8%
Pokhara	7.2%	11.0%	16.1%	24.6%	38.5%
Rara Lake	0.7%	1.6%	2.3%	3.4%	5.1%

Table 8: Expected loss in 100 years at different percentiles for MUR+ST/LWAL+DNO/H:3, considering varying building capacity

Figure 14: Expected loss in different timeframes for MUR+ST/LWAL+DNO/H:3 at different percentiles (5%, 25%, 50%, 75%, and 95%) in Kathmandu, shown as absolute values (left) and normalised values (right)

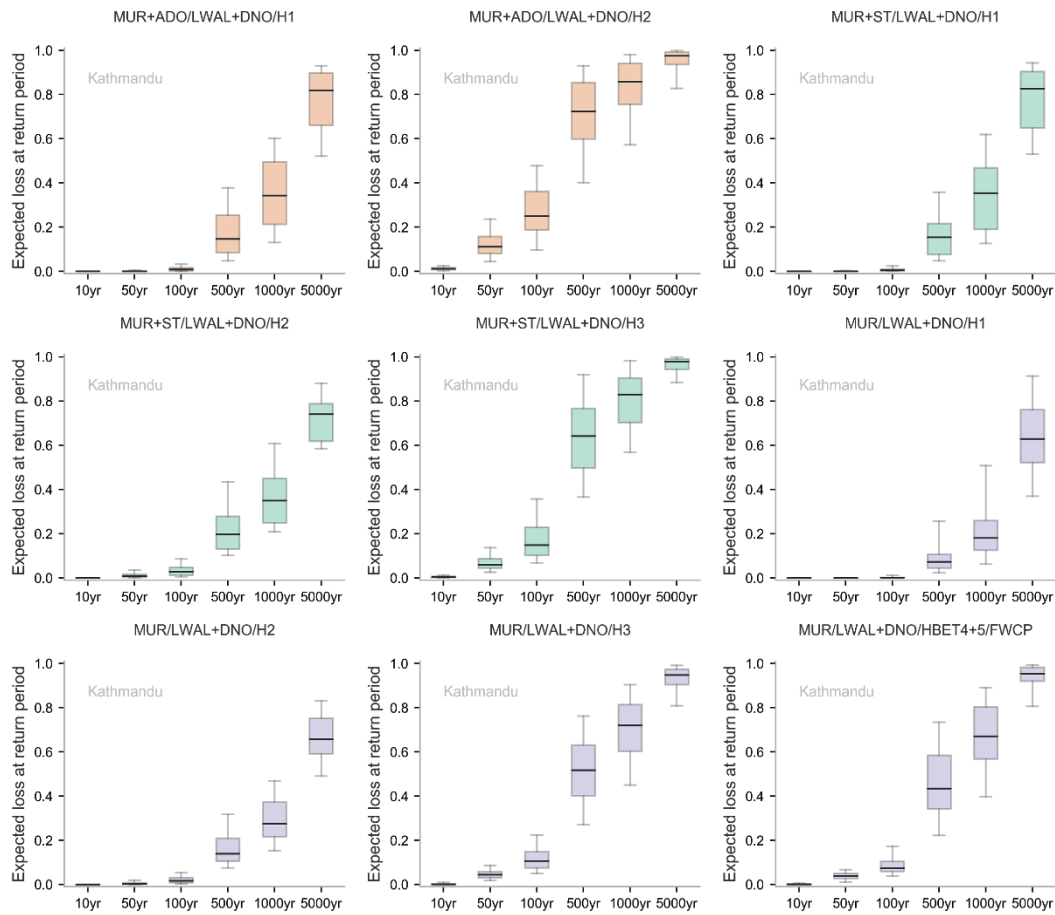

Figure 15: Expected loss in different timeframes for all considered building typologies at different percentiles (5%, 25%, 50%, 75%, and 95%) in Kathmandu

4.4. DAMAGE STATE VARIABILITY

The derivation of fragility curves also relies on the identification of different damage states (e.g., slight, moderate, extensive, complete) and the corresponding criteria or thresholds for a building to enter those damage states. However, the determination of these thresholds has both epistemic uncertainty (e.g., how many damage states are chosen) and inherent randomness (e.g., a building may enter 'slight' damage at different levels of response). This uncertainty was incorporated by including additional variability in the demand threshold at which each sequential damage state was entered. An additional dispersion of 0.3 was included (Casotto, *et al.*, 2015; Silva, *et al.*, 2013; FEMA, 2014), which was combined with the best-fit regression dispersion using the SRSS method (i.e., square root of the sum of the squares).

Comparisons of the resulting fragility and vulnerability models derived for an example building typology are shown in Figure 16 and Figure 17, respectively.

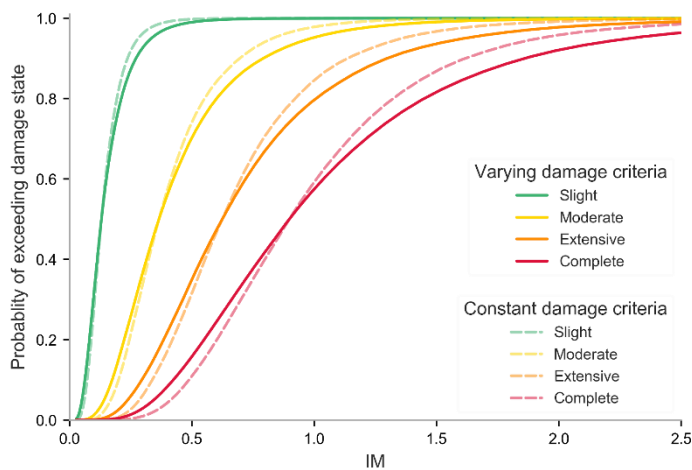

Figure 16: Resulting fragility curves with and without varying damage criteria for MUR+ST/LWAL+DNO/H:3

Figure 17: Resulting vulnerability curves with and without varying damage criteria for MUR+ST/LWAL+DNO/H:3

The effect of this additional layer of uncertainty on the expected losses are presented in Table 9 and Table 10. In these results, the additional damage state variability (or demand variability) is included on top of the building capacity variability outlined in the previous section. Percentiles of loss exceedance curves are shown in Figure 18.

Location	5%ile	25%ile	50%ile	75%ile	95%ile
Bharatpur	0.17%	0.28%	0.39%	0.58%	0.87%
Janakpur	0.40%	0.61%	0.80%	1.11%	1.59%
Kathmandu	0.37%	0.56%	0.74%	1.02%	1.46%
Pokhara	0.40%	0.60%	0.80%	1.10%	1.57%
Rara Lake	0.05%	0.10%	0.14%	0.22%	0.36%

Table 9: Average annual losses for MUR+ST/LWAL+DNO/H:3, considering both varying building capacity and varying damage criteria

Location	5%ile	25%ile	50%ile	75%ile	95%ile
Bharatpur	3.5%	5.6%	8.0%	11.7%	18.0%
Janakpur	8.8%	13.5%	19.2%	27.7%	40.8%
Kathmandu	8.1%	12.4%	17.6%	25.6%	38.0%
Pokhara	8.7%	13.3%	19.0%	27.4%	40.4%
Rara Lake	1.0%	2.0%	2.7%	4.1%	6.0%

Table 10: Expected losses in 100 years for MUR+ST/LWAL+DNO/H:3, considering both varying building capacity and varying damage criteria

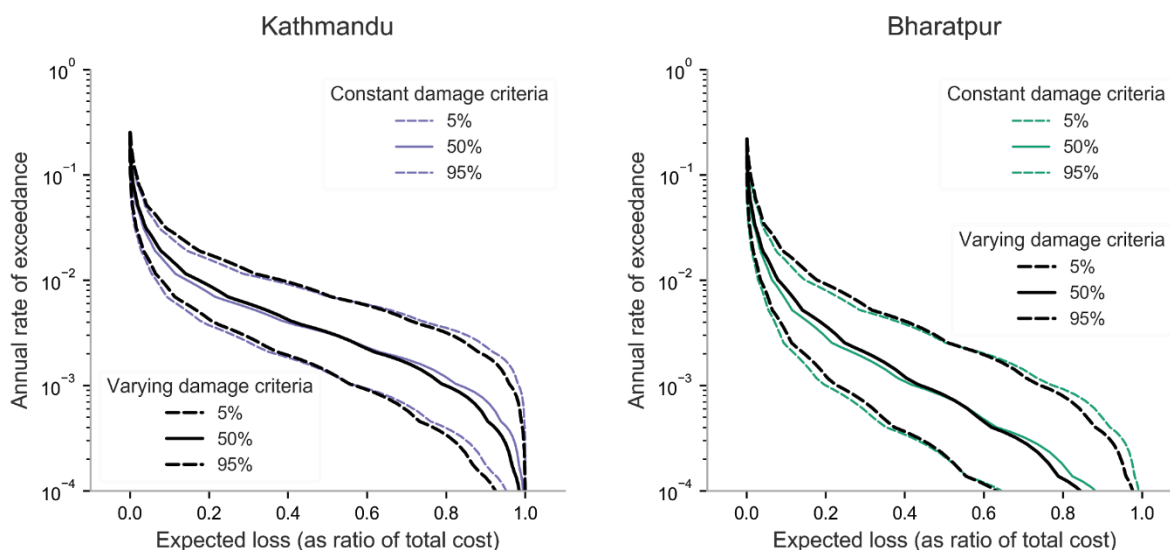

Figure 18: Annual loss exceedance curves for MUR+ST/LWAL+DNO/H:3 in Kathmandu and Bharatpur, with and without varying damage criteria

As seen from the results shown, inclusion of variability in the damage criteria further increases the range of uncertainty. Notably, the values at each percentile tend to shift to be higher (i.e., larger value of loss) for rare return periods, and lower for more frequent return periods. This implies that loss estimates that do not include uncertainty in the damage criteria could be systematically over or underestimated. However, the range of increase is not as substantial as the total uncertainty already included from inclusion of both the hazard input variability and the building capacity variability.

4.5. LOSS RATIO VARIABILITY

Damage states are mapped to economic losses in order to construct vulnerability curves and calculate loss estimates (e.g., average annual, probable maximum). The mapping could use expected values (i.e. singular values) for each damage state, or a distribution of losses. This report investigated the impact of either option on the resulting vulnerability models.

Similar to the other areas of uncertainty, damage-based loss ratios have both inherent randomness and epistemic uncertainty. Damage-to-loss models have been proposed using a variety of distribution types (e.g., lognormal, Beta) and underlying data (e.g., insurance claims). For this study, a Beta distribution was investigated, due to further flexibility in its shape to account for concentration of loss ratios close to 0 or 1, as evidenced in some past earthquake events (Silva, 2019; Peiris, *et al.*, 2014; Shome, *et al.*, 2012). The parameters assumed are shown in Table 11, with the corresponding cumulative density functions shown in Figure 19.

Damage state	Mean	CoV	Alpha	Beta
Slight	0.05	0.3	10.5	199.6
Moderate	0.20	0.2	19.8	79.2
Extensive	0.60	0.1	39.4	26.3
Complete	1.00	0.0	--	--

Table 11: Assumed Beta distribution parameters for probabilistic loss ratio for each considered damage state

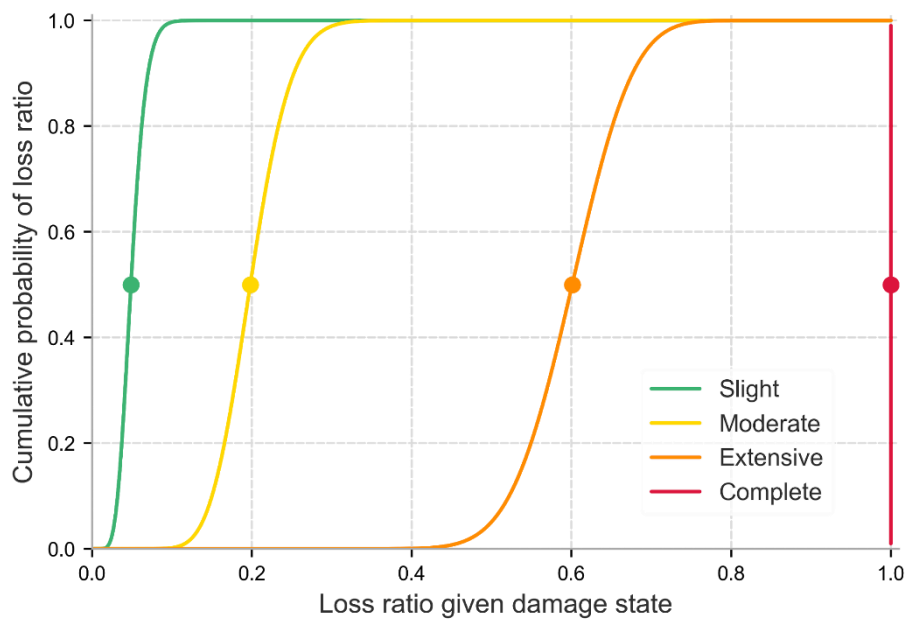

Figure 19: Assumed Beta distributions for probabilistic loss ratio for each considered damage state

The same fragility and vulnerability derivation process was followed using the constant and varying damage-to-loss assumptions, with results shown in Figure 20.

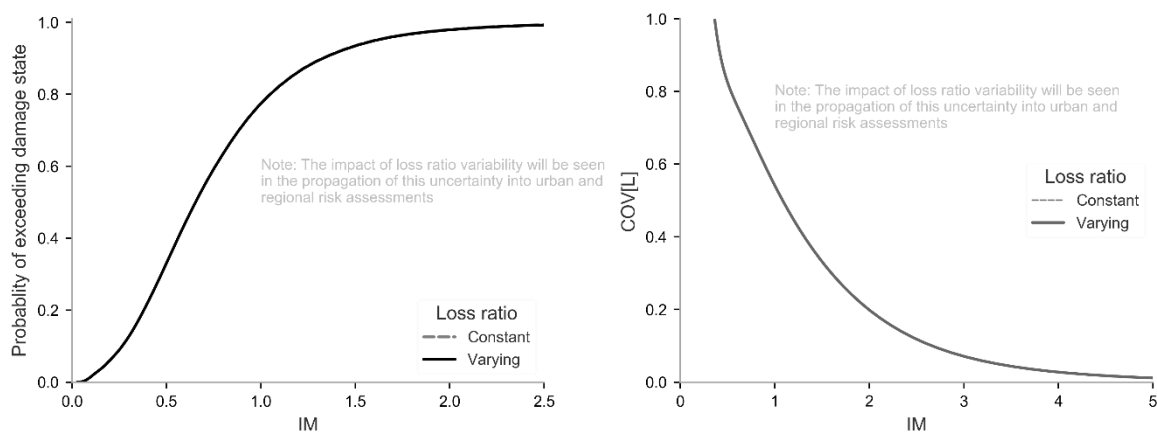

Figure 20: Comparison of resulting vulnerability curve (left) and coefficient of variation of expected loss (right) for varying intensity levels, with and without loss ratio variability for MUR+ST/LWAL+DNO/H:3

While the results in Figure 20 give the illusion that incorporation of uncertainty in the damage-to-loss ratio does not have an impact, further work to propagate the varying damage-to-loss ratios to urban and regional risk assessment will show a difference. This is because this report is limited to investigation on the vulnerability models, which themselves show central (i.e., median) numerical estimates of loss. In an urban or regional assessment, the uncertainty can be included such that different buildings within a spatial area can have differing loss values in a given realisation. Once aggregated across the considered spatial region and number of realisations, a larger distribution of disaster risk loss results is anticipated.

5. Next steps

This report investigated the propagation of uncertainty on vulnerability models, which are used as a component of disaster risk assessment. While this is informative, and considering different aspects of uncertainty has shown to have a significant impact on the derived analytical vulnerability models, the impact on disaster risk assessment results is not yet demonstrated. The next step for this work package is to investigate the propagation of these uncertainties on urban and regional risk assessments. To do so, scenario and fully probabilistic risk assessments will be carried out for the urban area of Kathmandu and the national area of Nepal. The results will be compared across the different cases shown in Table 12.

Case	Uncertainty included in...		
	Capacity curve	Damage measure	Loss ratio
1			
2	✓		
3	✓	✓	
4		✓	
5		✓	✓
6			✓
7	✓		✓
8	✓	✓	✓
