Abstract

Six methods of determining regional values of average annual actual evapotranspiration from a mixed vegetation surface are applied to observations from 20 climatological stations in Malawi. Three of the methods are judged unsuitable because they either over or under-estimate substantially or do not exhibit the gradual increase in actual evapotranspiration with increasing rainfall: these methods are equilibrium evaporation and two others, Brutsaert-Stricker and Bouchet, based on the complementary evaporation concept. The remaining three methods are recommended for use in Malawi: catchment waterbalance, which is used as a yardstick against which the other methods are compared, gives values of actual evapotranspiration which vary between 39 and 67% of short grass potential evaporation at the same station; soil moisture recharge demonstrates the least scatter but suffers the disadvantage of requiring independent calibration; the last of the methods, a new empirical approach expressing actual evapotranspiration as the difference between the values of the constituent energy and aerodynamic terms of the Penman formula for short grass potential evaporation, gives a countrywide mean 9% lower than that of the catchment waterbalance.

1. Introduction

1.1 TOPOGRAPHY

Malaŵi is located at the southern end of one limb of the East African Rift Valley system which dominates the topography of the country. Lake Malaŵi, the third largest lake in Africa, occupies the northern two thirds of this section of the rift (Figure 1.1). The lake is at an altitude of 470 m and its only outlet, the River Shire, drains southwards to the lower rift valley at 90 m altitude before joining the River Zambezi. In subsequent sections of this report two parts of the rift valley will be mentioned frequently: the region adjacent to Lake Malaŵi is called the 'lakeshore', whilst the region extending southwards from approximately the River Shire's confluence with the River Mwanza is called the 'Lower Shire Valley'.

All rivers in Malaŵi drain eventually into the River Shire (Fig. 1.1), except those in the eastern part of the country. Here there is an extensive catchment area draining into Lake Chilwa, from which there is no outlet, and a smaller area draining into the lakes and rivers of Mozambique.

The topography of Malaŵi is particularly varied (Figure 1.2) but the country may be divided into tour major physiographic zones as follows:

- a) plateau
- b) highland
- c) rift valley plains
- d) escarpment

The plateau is at an altitude of between 900 and 1200 m and features broad undulating plains. The underlying rocks are those of the Precambrian Malaŵi Basement Complex. The climate is temperate and the original vegetation is Brachystegia-Julbernadia woodland. These are the most densely cultivated regions of the country and little of the original woodland remains. An important feature of the plateau are the dambos, broad grass-covered swampy valleys which overlie impervious strata and which become saturated with water during the rainy season; they exhibit a peculiar hydrological behaviour which sets them apart from all other types of catchment within the country.

The highland rises abruptly from the plateau reaching altitudes of between 2100 and 3000 m. The underlying rocks are granites, phyllonites or syeno-granites. The climate is cool and the natural vegetation is forest relics and open grassland. These areas are now either forest or game reserves, partly covered with exotic trees.

The plains of the rift valley floor are gently sloping and of very low relief. They extend along parts of the lakeshore and upper River Shire valley at levels of less than 600 m and fall to less than 100 m above sea level in the Lower Shire valley; they are covered mainly by alluvial deposits of the Quaternary Age. The climate is semi-tropical and the original vegetation is mixed savannah woodland. In this zone the most favourable soils have been developed into irrigated rice and sugar schemes.

Figure 1.2 Major physiographic zones of Malaŵi (after Smith-Carington and Chilton, 1983)

1.2 HYDROMETEOROLOGY

The variation in the average annual values of the primary hydrometeorological variables measured on the catchments used in this study is summarized in Table 1.1. However the rugged topography, range of altitude and the temperature reservoir of Lake Malaŵi ensure that climatic conditions are complex.

| Variable | Mcan (mm) | Minimum (mm) | Maximum (mm) |
|---------------------------|--------------|-----------------|-----------------|
| Rainfall | 1130 | 710 | 2100 |
| Runoff | 309 | 37 | 980 |
| Actual evapotranspiration | 817 | 630 | 1100 |

Table 1.1 Range of average annual values of main hydrometeorological variables values of main values values of main values values of main values values

The average annual runoff expressed as a percentage of the average annual rainfall varies between 4 and 54%. The lower runoff occurs in the drier parts of the plateau, where the streams dry up or remain as stagnant pools for between one and six months every year. Higher runoff occurs in the highland, where most streams are perennial.

An isohyetal map of mean annual rainfall, prepared by Agnew and Stubbs (1972), is reproduced in Figure 1.3. In most areas the rainy season extends from November to March, with the maximum intensity occurring in January, resulting from the general migration of the Inter-Tropical Convergence zone. Convective rainfall over the land normally occurs in the afternoon in the form of local thunderstorms. However, along the lakeshore, storms are common in the early morning due to convection over the relatively warmer waters of the lake. Rainfall is also strongly influenced by orography; the highland and escarpment directly exposed to the prevailing south-easterly winds receive an annual rainfall which can be three times that of adjacent areas. This effect is particularly marked in April, with the northwards retreat of the Inter-Tropical Convergence Zone, when these areas receive their maximum monthly rainfall while all other areas receive only light showers.

Two other types of rainfall also occur. Firstly, occasional torrential downpours are associated with the movement inland of tropical cyclones from the Indian Ocean. Secondly, inflow of cool maritime air causes orographic rain, known locally as 'chiperoni', over south-east facing highland and escarpment; this effect if particularly apparent when contrasted with the otherwise fine weather of the dry season, which extends from May to October.

Temperature is closely related to altitude; latitude has much less significance.

Figure 1.3 Mean annual rainfall (after Agnew and Stubbs, 1972)

Van der Velden (1980) showed that the mean monthly temperature ranges from 10 to 16°C in the highland, from 16 to 26°C on the plateau, 20 to 29°C along the lakeshore and 21 to 30°C in the Lower Shire valley. The annual temperature range at stations along the lakeshore is subdued due to the ameliorating influence of Lake Malaŵi.

1.3 PREVIOUS EVAPORATION STUDIES IN MALAŴI

The earliest study was that of Pike (1962) who used the Penman formula to estimate monthly values of open water evaporation at 23 stations using data spanning the years 1952-1961. From these results he constructed a map of Malaŵi showing isolines of average annual open water evaporation in imperial units.

The World Meteorological Organization (1976) undertook a water resources assessment of Lake Malaŵi. Initially they examined the waterbalance of the smaller Lake Chilwa basin; by comparing their estimate of lake evaporation with adjacent evaporation pan records, they were able to transfer their results to the larger basin and estimate the average annual evaporation from Lake Malawi as 1610 mm.

Van der Velden (1979) collated the measurements from 38 pan evaporation stations and found that the value of pan evaporation was closely related to topography. The average annual pan evaporation ranges from 1500-2000 mm on the plateau and up to 2000-2200 mm along the lakeshore and in the Shire Valley; values below 1500 mm are found in areas of high and prolonged rainfall.

The Malaŵi Meteorological Service has derived Penman estimates of both open water evaporation and potential evapotranspiration at 19 stations using data from 1972-1979 (Dandaula, 1979). The open water evaporation estimates are similar to, but slightly lower than, the pan evaporation estimates but differ from the corresponding estimates of open water evaporation obtained by Pike, mentioned previously. The potential evapotranspiraton estimates range from1100-1700 mm, depending on altitude.

The study by Smith-Carington (1983) differed from the others in that it examined actual rather than potential evapotranspiration. She estimated that this variable took a value of 780 mm over the total plateau area of the Bua catchment (Fig. 1.1) based on a consideration of vegetation types and moisture conditions, although there will be large spatial variations depending on topographic position.

1.4 AIM OF PRESENT STUDY

The aim of this study is to provide methods for estimating actual evapotranspiration in Malaŵi. In this report justification is provided to support the application of these methods only under the following restraints:

- a) the evaporating surface is mixed vegetation as described in Section 1.1 (a mixture of cultivated fields, open grassland, pockets of woodland, small irrigation schemes etc.); a continuous vegetation surface, such as a forest canopy, has not been examined
- b) the estimate is of annual values of actual evapotranspiration although all the proposed methods use monthly observed data as input (and several of the methods can provide monthly estimates of actual evapotranspiration) all the comparisons and supporting evidence described in this report have been directed towards examining average annual values
- c) the estimate is primarily a regional, rather than a site-specific, value of actual evapotranspiration - although the comparison between the methods is undertaken using a definitive network of climatological stations, the most reliable method, against which the others are adjudged, is based on a non-site-specific catchment waterbalance.

The majority of previous evaporation studies in Malaŵi have been directed towards estimating open water evaporation and potential evapotranspiration; actual evapotranspiration has not been examined in any depth.

Open water evaporation estimates, derived from either climatological station or evaporation pan data, are used to compute evaporative losses from large open-water surfaces, such as lakes or reservoirs. Potential evapotranspiration estimates are used to determine water use, i.e. evapotranspiration, or irrigated or rainfed crops. Irrigation engineers and agricultural hydrologists have devised various empirical methods for relating actual evapotranspiration to potential. However, because of the moisture deficit which builds up in the soil during the long dry season in Malaŵi, values of actual evapotranspiration of non-irrigated vegetation will, in practice, be of the order of half those of potential evapotranspiration in the same region.

It would prove extremely useful to possess reliable methods for estimating actual estimating actual evapotranspiration directly from observed data. Such methods could be used to determine:

- a) the water use of rainfed and irrigated crops, without the use of empirical factors
- b) the waterbalance of catchments; the difference between the rainfall and actual evapotranspiration, is the sum of the surface runoff and the recharges to soil moisture and groundwater storages.

1.5 METHODS OF ANALYSIS

The study commences with a review of the variation of potential evapotranspiration estimated from observations drawn from a network of 20 climatological stations spread throughout the country. This leads to a classification of the stations according to the respective sizes of the average annual value of their energy and aerodynamic terms, constituents of the Penman formula for estimating short grass potential evaporation.

In the main body of the report, the suitability of six methods of estimating actual evapotranspiration, for use under the soil-vegetation complex of this region of Central Africa, is examined. Of these, five are well-established methods, the last is a new method first proposed in this study.

The first method is a simplified catchment waterbalance applied to rainfall and runoff data from 38 catchments in Mala⁴vi (Drayton *et al.*, 1980). Neglecting annual changes in groundwater and soil moisture storage enables average annual actual evapotranspiration to be expressed in terms of the average annual rainfall. The second method introduces the concept to soil moisture recharge (Thornthwaite, 1948), which is applied to monthly rainfall data and potential evapotranspiration; the value of soil moisture recharge is found ideally from an independent field survey.

The remaining four methods determine actual evapotranspiration directly from climatological data, expressing it in terms of the constituent energy and aerodynamic terms of the Penman formula for short grass potential evaporation; one of the methods also requires values of the outgoing long-wave radiation. One of these methods is that of equilibrium evaporation (Denmead and McIlroy, 1970); the other three are based on the concept of complementary evaporation, and include the methods of Bouchet (1963), Brutsaert and Stricker (1979), and the new so-called Difference method.

Values of average annual actual evapotranspiration were determined using each of the six methods for data observed at the 20 climatological stations. Accuracy of all methods was assessed by comparing their results with those of the catchment waterbalance, which was considered the most reliable.

2. Rainfall and potential evaporation

This section will examine the variability of rainfall and potential evaporation throughout the country, prior to investigating the different methods of estimating actual evaporation in the main body of the report.

2.1 CLIMATOLOGICAL STATIONS

The basic records used in this study to estimate evaporation are drawn from observations, established by the Malaŵi Meteorological Service, which are situated throughout the country (Figure 2.1) at altitudes ranging from 58 m at Makhanga to 1633 m at Dedza (Figure 2.2). The latitude, longitude and altitude listed in Table 2.1 are provided by the Meteorological Service. In his study on pan evaporation in Malaŵi, Van der Velden (1979) lists the same statistics; these show slight differences in latitude and longitude and larger differences in some of the altitudes. As latitude and altitude form an important input to the calculation of potential evaporation, these discrepancies should be resolved in future to improve the accuracy of the estimates.

Six of the stations lie close to the shore of Lake Malaŵi and together with two further stations, Ngabur and Makhanga located in the Lower Shire Valley, form the group of stations described as in the 'rift Valley'. The remaining 12 stations, all at higher altitudes, form the group of stations on 'upland' areas.

2.2 ESTIMATING POTENTIAL EVAPORATION

Potential evaporation (E_p) was estimated by the well-known Penman formula:

$$E_{p} = \frac{\Delta}{\Delta + \gamma} R_{n} + \frac{\gamma}{\Delta + \gamma} f (U_{2}) (e_{s} - e)$$
(2.1)

All symbols are explained in the Notation at the beginning of the report.

In this study the semi-empirical formula for the estimation of net radiation (R_n) is used. This has been applied by de Bruin and Stewart (1983); they, in turn, adopted it from Doorenbos and Pruitt (1977) who proposed a relationship between sunshine hours and solar radiation suitable for tropical latitudes. It reads:

$$R_n = R_a(1 - r) (0.25 + 0.50 \frac{n}{N} - \sigma T_a^4 (0.1 + 0.9 \frac{n}{N}) (0.34 - 0.44 \sqrt{e})$$
 (2.2)

To estimate Penman short grass potential evaporation $(E_p = E_{PN})$ the albedo r was set equal to 0.25. To estimate Penman open water evaporation $(E_p = E_p)$ the albedo was set to 0.05.

The wind function $f(U_2)$ is the same as that applied by Brutsaert and Stricker

Table 2.1Climatological stations (records published by Malaŵi
Meteorological service)

Figure 2.2 Altitude of climatological stations

(1979) in one of their versions of the Penman formula. Expressed in units of W m^{-2} mb⁻¹ the exact expression used was:

$$f(U_2) = 7.4 \ (1.0 + 0.54 \ U_2) \tag{2.3}$$

where U_2 is the wind speed (m s⁻¹) at a height of 2 m. The monthly mean wind run over 24 hours was used, with no additional modification incorporating the ratio between day and night-time wind speeds. Before substitution in Equation 2.1 the units of $f(U_2)$ were converted to mm day⁻¹ mb⁻¹ to make them compatible with the net radiation term expressed as a water equivalent.

Appendix 1 contains in greater detail the practical background to the calculation of potential evaporation for Malaŵi; it discusses how certain minor variable were calculated, anomalies discovered and corrections made to the data before processing.

The four types of basic data required for using Penman's formula are temperature, humidity, wind run and sunshine hours. Monthly mean climatological data of this form, together with rainfall, are published by the Malaŵi Meteorological Service (1970-1978). When this study began there were nine years of records (1970-1978) for all stations except Ngabu which had records for six years (1973-1978) and Dwangwa which had records only for 1973 and 1979 and which was subsequently closed.

Monthly values of E_{PN} and E_o were estimated by Equation 2.1 using the appropriate value of albedo. Average annual values of R, E_{PN} and E_o , calculated over the nine years of record, are listed in Table 2.2 Average monthly values of the same variables for each of the 20 stations are given in Appendix 2. Variations in average annual values of rainfall and potential evaporation, and also the energy term and aerodynamic term are shown in Appendix 3.

2.3 VARIATIONS IN RAINFALL

Average annual values of rainfall (R) taken from Table 2.2 are also shown in Figure A3.1. For upland stations R varies without major inconsistencies from a low of 898 mm at Lilongwe to 1544 mm at Mimosa. Amongst rift valley stations low values are recorded to the south of the lake, the lowest value being 722 mm at Makhanga. In contrast, along the western lakeshore, rainfall demonstrates considerable variation, ranging from 1147 mm at Karonga to 1759 mm at Nkhota Kota, but without any smooth progression from north to south.

The coefficients of variation listed in Table 2.2 should provide a measure of the variation of the annual values of rainfall at each station; in general, rainfall varied considerably from year to year. Fig. A3.2 shows that these coefficients are consistent both for the two stations located in the Lower Shire Valley and for all the upland stations except Chitedze and Chileka which have low and high values respectively. Along the lakeshore Nkhota Kota and Nkhata Bay, which have the highest values of average annual rainfall, show

year-to-year variation similar to that of upland stations. However lakeshore stations with lower rainfall show much higher year-to-year variation.

2.4 VARIATIONS IN POTENTIAL EVAPORATION

The spatial variation over Malaŵi of average annual values of evaporation estimates, $(E_{PN} \text{ and } E_o)$ taken from Table 2.2 are shown in Figures A3.3 and A.3.4. In general higher values of Penman short grass potential evaporation,

 $(E_{\rm PN})$ are recorded along the rift valley floor with a maximum of 1840 mm at Ngabu; lower values are found on the upland areas, with a minimum of 1316 mm at Mzuzu. Exceptions to these general trends are lower values of 1618 and 1534 mm at Dwangwa and Nkhata Bay, and higher values of 1769 and 1816 mm at Chitipa and Chileka.

Since the formula for Penman open water evaporation (E_0) and that for E_{PN} differ only to the extent of the value of the albedo chosen, their values show a similar pattern of spatial variability, but with maximum and minimum estimated values for E_0 of 2297 mm at Karonga and 1710 mm at Mzuzu. Values of E_{PN} expressed as a fraction of the corresponding value of E_0 for each climatological station vary between 76 and 81%; because of this small range, some of the comments made in subsequent sections about properties of E_{PN} will also hold for E_0 . However, to avoid considerable repetition, comments will be confined to E_{PN} in the remainder of this report and the reader, armed with corresponding values of E_{PN} and E_0 in either Table 2.2 or Appendix 2, is encouraged to deduce the similar relationships for E_0 .

The small coefficients of variation listed in Table 2.2 indicate that there is very little change from year to year in annual values of $E_{\rm PN}$ and $E_{\rm o}$. Chitipa station is notable in possessing particularly low variation, which may be a symptom of a very stable climate.

2.5 THE CONSTITUENT ENERGY AND AERODYNAMIC TERMS

To look more closely at the variability of the Penman short grass potential evaporation estimate (E_{PN}) it is useful to break it down into its constituent components:

$$E_{PN} = M_e + M_a \tag{2.4}$$

where Me, the energy term, is defined as:

$$M_e = \frac{\Delta}{\Delta + \gamma} R_n$$
 (2.5)

and M_a, the aerodynamic term, is defined as:

$$M_{a} = \frac{\gamma}{\Delta + \gamma} f(U_{2}) (e_{s} - e)$$
(2.6)

For each climatological station, average annual values of M_e and M_a are listed in Table 2.3 (see also Figures A3.5 and A3.6); average monthly values are given in Appendix 2. The mean average annual values of M_e and M_a for the two main groups of stations are given in Table 2.4.

Examination of the spatial variation of M_e showed that all the higher values were found at rift valley stations; for this group the range is small, 1250 to 1291 mm, and there is no discernible difference in values between lakeshore and Lower Shire Valley stations. The mean value of M_e for upland areas is 11% less than that of the rift valley (Table 2.4), and individual values exhibit rather more spatial variation ranging from 1075 to 1170 mm. The coefficients

| | | M _e | М | I |
|----------------|------|----------------|------|----------------|
| Climatological | Mean | cv | Mean | - CV (%) |
| Station | (mm) | (%) | (mm) | |
| Bvumbwe | 1079 | 1.6 | 352 | 8.2 |
| Chichiri | 1106 | 1.5 | 406 | 17.5 |
| Chileka | 1170 | 2.1 | 646 | 8.2 |
| Chitedze | 1127 | 2.0 | 431 | 9.2 |
| Chitipa | 1170 | 1.1 | 599 | 2.8 |
| Dedza | 1075 | 1.8 | 397 | 5.7 |
| Dwangwa | 1259 | 2.8 | 359 | 13.4 |
| Karonga | 1291 | 0.9 | 544 | 6.8 |
| Lilongwe | 1117 | 2.4 | 461 | 9.4 |
| Makhanga | 1290 | 2.1 | 494 | 9.0 |
| Makoka | 1104 | 1.8 | 402 | 9.6 |
| Mangochi | 1250 | 2.0 | 556 | 6.7 |
| Mimosa | 1128 | 1.9 | 276 | 6.1 |
| Mzimba | 1157 | 2.3 | 356 | 6.1 |
| Mzuzu | 1109 | 2.3 | 208 | 7.5 |
| Ngabu | 1267 | 1.9 | 571 | 9.0 |
| Nkhata Bay | 1261 | 2.0 | 272 | 9.3 |
| Nkhota Kota | 1250 | 1.9 | 510 | 5.6 |
| Salima | 1268 | 2.6 | 546 | 9.2 |
| Thyolo | 1129 | 23 | 299 | 4.0 |
| Mean | 1180 | 2.0 | 434 | 8.2 |

Table 2.3 Average annual values of the energy term M_e and aerodynamic term M_a constituents of the Penman short grass potential evaporation E_{PN}

Table 2.4 Mean average annual values of energy term M_e and aerodynamic term M_a for the two groups of climatological stations

| Term | Rift valley stations Mean (mm) | Upland area stations Mean (mm) |
|------------------------------------|--------------------------------------|--------------------------------------|
| Energy term (M) | 1267 | 1123 |
| Aerodynamic term (M _a) | 482 | 403 |

of variation in Table 2.3 demonstrate that there is extremely little change from year to year in M_e at all stations, with the least variation being shown by Karonga and Chitipa.

Values of the aerodynamic term (M_a) are considerably smaller than those found for the energy term (M_e) varying from 19 to 55% of the corresponding value. Despite these lower absolute values they exhibit greater spatial variation, ranging from 208 to 646 mm. Although the mean value of M_a for the group of upland area stations is 16% less than that for the Rift Valley stations (Table 2.4), the distinction is not so clear-cut as was found for M_ previously; not all values of M_a in the rift valley exceed those on upland areas. Values of M_a appear to be depressed below 300 mm in the two areas centred respectively on Thyolo-Mimosa and Nkhata Bay-Mzuzu, with a least value of 208 mm estimated for Mzuzu; these areas exhibit for major part of the year a moist climate suitable for tea cultivation. On the other hand the highest values of M_a occur at Chitipa (599 mm) and Chileka (646 mm), both of which are located on the leeward side of high ground, so a possible explanation is warm dry air descending over the stations. Table 2.3 shows that the coefficients of variation for M₂ are several times larger than those for Me, although their mean values are much smaller, as noted previously; this implies that changes in M_e and M_a both contribute substantially to the year-to-year variation in E_{PN} . Chitipa station is again noteworthy for its extremely low coefficient of variation, whilst high values at Dwangwa and Chichiri led to further checks on the basic climatological data; that at Dwangwa arises from a genuine large change in vapour pressure deficit between the two years of data, whilst that at Chichiri cast doubts on the homogeneity of the wind records at this station.

2.6 CLASSIFICATION OF CLIMATOLOGICAL STATIONS

An alternative way of highlighting these variations in energy and aerodynamic terms, for each of the 20 climatological stations, is shown in Figure 2.3. The plotted points appear to lie in a number of distinct groups and these differences may be used to draw up a classification with stations within each class having similar values of M_e and also M_a (Table 2.5). The name 'regions' cannot be used, as points within a particular class are not necessarily contiguous. Whilst Classes 1 to 3 are distinct, the border between Classes 4 and 5 is blurred and a subjective decision was made to include Bvumbwe and Mzimba in Class 4 rather than Class 5, based on their values of M_a . This classification will be used later in the soil moisture recharge chapter to distinguish the climatic properties of different stations.

| Class No | Climatological stations in class | M _e Mcan (mm) | M _a Mean (നന) |
|----------|-------------------------------------|--------------------------------|--------------------------------|
| | Karonga | 1269 | 537 |
| | Makhanga | | |
| | Mangochi | | |
| | Ngabu | | |

3 Catchment waterbalance

3.1 SIMPLIFIED WATERBALANCE

The waterbalance of a catchment over given period may be expressed in terms of the main variables as:

$$\Sigma R = \Sigma Y + \Sigma E + \delta V + \delta W$$

(3.1)

where R is rainfall

- Y is yield i.e. surface runoff
- E is actual evaporation
- V is soil moisture storage
- W is groundwater storage

and Σ and 5 represent sum and difference respectively.

Although the changes in soil moisture and groundwater storage in Malaŵi during a typical year may be substantial, it is suggested that the changes from one year to the next are small. Regarding soil moisture storage, towards the end of the dry season after several months with little rainfall, the vegetation will have increasing difficulty in abstracting available water, and soil moisture deficits will tend asymptotically towards an upper limit. Regarding groundwater storage, Smith-Carington and Chilton (1983) found that, for boreholes with the longest and most frequent records, there was no evidence of declining water levels over the period 1971-1981 in either the weathered basement or alluvial Therefore, provided the period for the waterbalance calculation is aquifers. chosen to be the 12 months commencing at the start of the rainy season and finishing at the end of the long dry season, and provided that a minimum of five years' records are used, the terms involving soil moisture and groundwater storage may be safely neglected. In this case the waterbalance may be expressed in the following simplified form:

AAR = AAY + AAE (3.2)

Where AAR is average annual rainfall AAY is average annual yield AAE is average annual actual evaporation.

Average annual yield is the average annual runoff volume expressed as a depth in millimetres per year over the catchment.

3.2 ACTUAL EVAPORATION ESTIMATED FROM CATCHMENT RECORDS

As part of their regional analysis of river floods and low flows, Drayton *et al.* (1980) examined the relationship between annual yield and rainfall for 47 catchments distributed throughout Malaŵi. Annual values of catchment yield

were calculated by summing the daily discharge data over the period 1 November to 31 October, which for Malaŵi runs from the start of the rainy season until the end of the following dry season. To estimate catchment annual rainfall a number of raingauges, normally two or three, were chosen on or near the selected catchment. Annual rainfall totals at these gauges for the same period as that above were weighted and combined using the Thiessen polygon method. Where either yield or rainfall data were missing for a particular year, this year was rejected, and some catchments were rejected entirely because there were no suitable raingauges. Further details of these analyses are given in Hill and Kidd (1980).

For the remaining 38 river gauging stations, catchment averages of annual rainfall and yield are listed in Table 3.1. Although for any given catchment the same years were used to determine the average values of rainfall and yield, it did not prove feasible to select a single period that was common to all the catchments. Therefore values listed in Table 3.1 should not be looked upon as forming long-term averages over a standardized period, for example three decades, that is often used as a common basis for rainfall records. Rather they should be regarded as preliminary estimates, which can be refined when longer records become available, of the magnitude of these hydrological variables in this part of Central Africa.

The values of rainfall and yield in Table 3.1 may be substituted into the simplified waterbalance, Equation 3.2, to provide, from their difference, estimates of catchment average annual actual evaporation, AAE. These values, also listed in Table 3.1, are superimposed on a map of Malaŵi in Figure 3.1, where they are located approximately at the centroid of the contributing catchment upstream of the river gauging station. Although there is a smooth progression between the majority of neighbouring estimates of actual evaporation, some anomalies are apparent where individual values differ substantially from those surrounding them. Values of 1077 and 1112 mm at station Nos 2.B.8 and 14.C.4. can be explained by the location of these catchments on the summit plateaux of inselbergs rising hundreds of metres above the surrounding plains. Variation of altitude between adjoining catchments may also explain the low estimate of 672 mm for station 2.B.22. However it is more difficult to provide a physical reason for the low value of 572 mm at station No. 15.A.8 and high values of 950 and 912 mm at station Nos. 7.E.2. and 7.F.2. respectively; a more likely reason is inaccuracies in the basic data, such as leakage of discharge past the river gauging station, paucity of raingauges leading to a poor estimate of catchment rainfall, or a wrong estimate of catchment area.

Inspection of Table 3.1 shows that in general values of actual evaporation vary between 572 and 1112 mm but the majority lie within the range 650 to 950 mm. The coefficient of variation of values from all the 38 catchments is 16%. In contrast values of rainfall lie approximately within the range 700 to 2100 mm, with a coefficient of variation of 28%, whilst values of yield lie approximately within the range 40 to 1000 mm, with a coefficient of variation of 80%. Consequently it may be deduced that, of the three hydrological variables under consideration, actual evaporation demonstrates the least variation throughout Mala%i.

their difference (After Drayton et al., 1980)

Figure 3.1 Estimated values of catchment average annual actual evaporation (mm)

3.3 YARDSTICK EQUATIONS FOR CALCULATING YIELD AND ACTUAL EVAPORATION

Drayton *et al.* (1980) examined the relationship between yield (AAY) and rainfall (AAR) for the 38 catchments listed in Table 3.1. A plot of AAY against AAR is shown in Figure 3.2; a regression through these points yielded the following expression:

$$AAY = 0.71 \quad AAR - 490$$
 (3.3)

with a correlation coefficient of R = 0.93 and a standard error of estimate of 90 mm.

Figure 3.2 Relationship between average annual yield AAY (mm) and rainfall AAR (mm) for 38 catchments in Malaŵi (after Drayton et al., 1980)

By substituting Equation 3.3 into the simplified waterbalance Equation 3.2 and rearranging, the average annual actual evaporation (AAE) may be expressed in terms of the average annual rainfall (AAR) as:

(3.4)

Because the deviation of an AAY value from the regression line (3.3) is reflected in an equal, but opposite, deviation of the corresponding AAE value from the regression line (3.4), it can be demonstrated that Equation 3.4 retains the same standard error of estimate (90 mm) as Equation 3.3, but the correlation coefficient is reduced to 0.72. Equation 3.4 shows that actual evaporation increases slightly with increasing rainfall. The expression is valid only within the rainfall range to 2100 mm, but Drayton *et al.* (1980) point out that it should be used with caution for rainfall of below 800 mm. Equations 3.3 and 3.4 are used in Figure 3.3 to demonstrate how average annual actual evaporation, yield and rainfall vary with increasing average annual rainfall; this format emphasizes that, for any given rainfall, the sum of the yield and actual evaporation is equal to the rainfall.

Figure 3.3 Relationship between actual evaporation, yield and rainfall from catchment waterbalance

Because of the high number of catchments examined and the wide range of average annual rainfall sampled, it is considered that the relationships shown in Fig. 3.3 provide, at present, the most reliable method, amongst those considered in this report, of estimating actual evaporation and yield given a knowledge of the rainfall at the location under consideration. They will be used as a yardstick against which other methods of estimating actual evaporation will be compared.

3.4 EXTRAPOLATION OUTSIDE RANGE OF OBSERVED RAINFALL

Because the relationships shown in Fig. 3.3 are valid only for a limited range of average annual rainfall, it is worthwhile to speculate what form they might take outside this range (Figure 3.4). At rainfalls lower than 700 mm it is moist for much of the year. As the rainfall continues to increase the actual evaporation will approach the potential evaporation, which itself has an upper limit governed by the intensity of net radiation (R_n) occurring at the evaporating surface (de Bruin, 1983). Estimated average annual values of R_n are listed in Section 5.3; for upland area stations it will be noted that this limit is approximately 1600 mm, whilst for rift valley stations it is 120 mm

Figure 3.4 Possible variation in average annual actual evaporation and yield outside the range of observed rainfall values

higher. At higher rainfalls still it is thought that actual evaporation will not increase at the same rate as the increase of rainfall, and their relationships will thus run parallel at their upper ends, as shown in Fig. 3.4

3.5 ACTUAL EVAPORATION ESTIMATED FOR CLIMATOLOGICAL STATIONS

Equation 3.4 may be used to estimate actual evaporation for a catchment located anywhere in Malaŵi where the average annual rainfall is known. In the extreme case where the catchment area tends to zero it will be assumed that the expression may also be used for estimates at a point, though possibly with less reliability. In particular, Table 3.2 lists the values given by this expression in estimating average annual actual evaporation (AAE) at the 20 standard climatological stations. In this table the values listed of average annual rainfall (AAR) are taken equal to the corresponding values of R listed in Table 2.2. Table 3.2 also lists the values of average annual yield (AAY) obtained by using Equation 3.3. Values are AAE and AAY found for Makhanga station should be used with care since AAR is less than 800 mm for this station.

| Climatological station | AAR | AAY | AAE |
|------------------------|------|------|------|
| | (mm) | (mm) | (mm) |

climatological stations

3.6 RATIO OF ACTUAL TO POTENTIAL EVAPOTRANSPIRATION

It is now feasible to make a preliminary survey of how much lower actual evapotranspiration is than potential evapotranspiration throughout the country. Values of actual evaporation (AAE) from Table 3.2 were expressed as a fraction of Penman short grass potential evaporation $(E_{\rm PN})$ from Table 2.2. These fractions, listed in Table 3.3, range from a minimum of 39% at Makhanga to a maximum of 67% at Mimosa, with a countrywide mean value of 51.4%. The variation of this fraction throughout the country is shown in Figure 3.5.

Table 3.3 Actual evaporation, AAE, estimated from catchment waterbalance, expressed as a fraction of Penman short grass potential evaporation, E_{PN}

| Climatological Station | AAE E _{PN} (%) | Climatological Station | AAE E _{PN} (%) |
|---------------------------|----------------------------|---------------------------|----------------------------|
| Bvumbwe | 57.0 | Makoka | 52.9 |

4. Soil moisture recharge

4.1 CONCEPT OF SOIL MOISTURE RECHARGE

To examine the annual waterbalance at a location where concurrent records of rainfall and potential evaporation exist, Thornthwaite (1948) introduced the concept of soil moisture recharge. This concept is particularly appropriate in climates, such as that in Malaŵi, where there is a single definitive annual rainy season separated from the following year's rainy season by a long dry season. Sutcliffe *et al.* (1981) employed this concept in their study of the Betwa River basin, a tributary of the Jamna, draining from the Deccan Plateau in central India. The following description is adopted from their paper, with minor modifications to suit Malaŵi conditions:

The annual waterbalance may be simplified by considering the seasonal cycle as a single period of water surplus during the rainy season and a single period of water deficit during the remainder of the year. During the rainy season period, monthly rainfall is greater than monthly potential evaporation for between two and six successive months, whereas during the rest of the year potential evaporation exceeds rainfall except in the occasional month. For a typical year Figure 4.1 shows the period of surplus of excess of rainfall over evaporation, and the subsequent period of deficit.

Figure 4.1 Schematic diagram of annual waterbalance cycle (after Sutcliffe et al., 1981)

The soil moisture recharge may be superimposed on this diagram, which then shows, to use the terminology of Thornthwaite (1948), a period of soil moisture recharge followed by a period of water surplus and then, after the end of the rainy season, a period of soil moisture utilization followed by a period of water deficit. This surplus supplies groundwater recharge as well as surface runoff. The soil moisture recharge clearly must equal the soil moisture utilization. Because the soil moisture storage is generally full at the end of the rainy season and always reaches wilting point during the dry season, the annual recharge will bring the storage from wilting point to field capacity throughout the rooting depth; this difference is defined as the 'root constant'. The soil moisture recharge should be reasonably constant from year to year in the absence of land-use change and may be considered as a first charge on the net rainfall, the surplus of rainfall over evaporation.

Furthermore, brief periods of drought during the rainy season and most periods of rain during the rest of the year, do not affect this cycle. The soil moisture deficit during dry periods in the rainy season will not approach wilting point, and the occasional rainfall surplus during April or May will not normally be sufficient to eliminate the soil moisture deficit. Thus, the net rainfall, or gross seasonal surplus, can be deduced by subtracting monthly potential evaporation from the monthly rainfall whenever the rainfall is the larger, and adding these monthly differences to give the net rainfall for the year.

Assuming that differences in groundwater storage between successive years are small in comparison with the annual groundwater recharge, the annual yield, which is the sum of surface and groundwater flows at the outlet of a catchment, is equal to the net rainfall less soil moisture recharge. Actual evaporation is assumed to equal potential evaporation during those months in which rainfall exceeds potential evaporation; during the remaining months actual evaporation is restricted by what moisture is available, and equals the sum of both the monthly values of rainfall together with the soil moisture utilization. The annual total of actual evaporation is thus estimated by subtracting the net from the gross rainfall and adding the total soil moisture utilization (which itself is equivalent to the soil moisture recharge).

4.2 ESTIMATION OF ACTUAL EVAPORATION AND YIELD

This verbal argument may be expressed algebraically by considering concurrent series of monthly rainfall and potential evaporation values spanning a period of K years. Let $R_{ij} E_{ij}$ represent the monthly rainfall, and E_{ij} the monthly potential evaporation,

where $i = 1, 2, 3, \dots, 12$ denotes months

and $j = 1, 2, 3, \dots, K$ denotes years.

Then, for any one particular month, the least of the two individual values of

rainfall and potential evaporation will be represented by min (R_{ij}, E_{ij}) where:

min
$$(R_{ij}, E_{ij}) = R_{ij}$$
 if $R_{ij} \in E_{ij}$ (4.1)

ог

The annual rainfall during year j is given by $\sum_{i=1}^{12} R_{ij}$, whilst the average annual rainfall over the complete period of record is given by $\frac{1}{K} \sum_{j=1}^{K} \sum_{i=1}^{12} R_{ij}$, which will be denoted in abbreviated form by $\overline{\Sigma} R_{ij}$. Similarly the abbreviated representation of the average annual values of potential evaporation E_{ij} and minimum min(R_{ij} , E_{ij}) are given by $\overline{\Sigma} E_{ij}$ and $\overline{\Sigma}min(R_{ij}, E_{ij})$ respectively.

Let S denote the annual value of the soil moisture recharge which will be assumed constant from year to year for any given location; this value will also be equivalent to the soil moisture utilization. The average annual actual evaporation determined by the soil moisture recharge method will be denoted by AAE' where:

$$AAE' = \sum \min (R_{ij}, E_{ij}) + S$$
(4.2)

and the average annual yield, denoted by AAY', as:

$$AAY' = \overline{\Sigma R_{ij}} - \overline{\Sigma \min (R_{ij}, E_{ij})} - S$$
(4.3)

4.3 COMPARISON WITH THE CATCHMENT WATERBALANCE METHOD

From general soil physical properties the value of soil moisture recharge (S) would be expected to lie within the range 50 to 250 mm for the soil and vegetation types encountered in Malaŵi (J.P. Bell, personal communication). Since there is, at present, no independent estimate of S available, two methods of estimating average annual actual evaporation, namely those of the catchment waterbalance and the soil moisture recharge, were compared to obtain an empirical estimate of S for locations in Malaŵi.

The comparison was made using records from the 20 climatological stations described in Section 2.1. At the majority of these stations monthly rainfall and potential evaporation data were available for 1970-1978; annual totals were obtained by summation over the period 1 January to 31 December. For individual years a more accurate estimate of the soil moisture recharge would be obtained by using the period 1 November to 31 October - the start of the rainy season to the end of the dry season. However, to estimate a mean value of S over the nine year-record, it was considered that this refinement could be safely neglected.

First, to initiate the soil moisture recharge method, monthly values of the

Penman estimate of short-grass potential evaporation (E_{PN}) were substituted for the E_{ij} values at each station. Average annual values of E_{PN} are listed in Table 2.2. Next, for each of the stations, ΣR_{ij} and $\Sigma \min (R_{ij}, E_{ij})$ were calculated. The former is exactly equivalent to the average annual rainfall (AAR) listed in Table 3.2; the latter is listed in Table 4.1 and differs,

| Table 4.1 | Individual station values of various variables arising from | m |

according to Equation 4.2, from the average actual evaporation (AAE') by the unknown value of S. Full details of a worked example of these calculations for a typical station are given in Appendix 4.

The second method of estimating AAE is the catchment waterbalance described previously in Section 3. Table 3.2 lists the values of AAE corresponding to the relevant values of AAR for each station. If it is assumed that the two estimates, AAE' and AAE, are equal, then it follows from Equation 4.2 that an estimate of the annual soil moisture recharge (S) is given for each station by:

$$S = AAE - \sum \min (R_{ij}, E_{ij})$$
(4.4)

Values of this difference are listed in Table 4.1. Exactly the same estimates of S may be obtained by assuming that the two estimates of average annual yield, AAY and AAY', calculated by the respective methods, are equal. In this case:

$$S = \overline{\Sigma R_{ij}} - \overline{\Sigma \min (R_{ij}, E_{ij})}$$
 AAY (4.5)

with values of $\overline{\Sigma} R_{ij}$ - $\overline{\Sigma} \min (R_{ij}, E_{ij})$ listed in Table 4.1 and AAY listed Table 3.2.

4.4 SOIL MOISTURE RECHARGE VARIATIONS

Estimates of soil moisture recharge obtained form Equation 4.4 vary between 34 and 209 mm with a mean value, rounded to the nearest 5 mm, of 120 mm. All values except three lie within the expected range suggested earlier. Comparison may also be made with the value of 175 mm deduced for the Betwa basin in India by Sutcliffe *et al.* (1981). Figure 4.2 illustrates the spatial variation of S throughout Malaŵi. Using the climatological classes defined in Section 2.6 this variation is summarized as:

| Class No | Mean value of S for class (mm) |
|----------|-----------------------------------|
| 1 | 113 |
| 2 | 133 |
| 3 | 114 |
| 4 | 152 |
| 5 | 61 |

If the values of S for the rift valley stations (class Nos. 1 and 2) are plotted against average annual rainfall (AAR), as in Figure 4.3, a weak relation giving an increase in S for increasing AAR results, i.e.,

S = 0.129 AAR - 40 (4.6)

Figure 4.2 Values of soil moisture recharge S (mm) obtained from comparing two estimates of average annual actual evaporation

Figure 4.3 Variation of annual soil moisture recharge with changes in average annual rainfall (a) rift valley stations (b) upland area stations

On the other hand, if values of S for the stations on upland areas in the remaining three classes are similarly plotted against AAR, a weak relation giving a decrease in S for increasing AAR results, i.e.,

$$S = -0.215 \text{ AAR} + 354$$
 (4.7)

One possible explanation of this observation is that, for the upland area stations, higher rainfall totals are caused partly by a longer rainy season (van der Velden, 1979) and, because of the consequent shorter dry season, soil moisture deficits are unable to develop to their fullest extent. In the rift valley along the lakeshore, on the other hand, higher rainfall totals are not necessarily accompanied by longer rainy seasons due to the climatic influence of the lake itself.

From the evidence presented above it is difficult to establish whether the variations in estimated values of S are genuine or arise from inadequacies in either the soil moisture recharge concept or the catchment waterbalance results. One particular inadequate aspect of the soil moisture recharge concept is addressed in the next section. Certainly there were few, if any, catchments included in the waterbalance records which represent only the rift valley as opposed to the escarpment areas draining down into it. To make this clear, an independent field survey to establish the moisture holding capacities of the soils throughout Malaŵi under different vegetative covers is required.

4.5 CONCEPT MODIFICATION AT LOW RAINFALL LOCATIONS

Another explanation for some of the lowest values found for S is that the soil moisture recharge concept described above may break down for certain stations with low values of net rainfall. The formula:

$$AAE' = \overline{\Sigma} \min (R_{ij}, E_{ij}) + S$$
(4.8)

is valid only if the net rainfall, given by $\Sigma R_{ij} - \Sigma \min(R_{ij}, E_{ij})$, exceeds the annual soil moisture recharge S. Where the net rainfall is less than S it is not normally possible to completely recharge the soil during the rainy season. In this case, the amount of moisture available in the soil at the end of the rainy season is equal to the net rainfall and not the value of soil moisture recharge proposed in the original concept. For such locations, therefore, AAE' is found from an alternative expression to Equation 4.8, namely:

$$AAE' = \left[\overline{\Sigma} \min \left(\mathbf{R}_{ij}, E_{ij} \right) \right] + \left[\overline{\Sigma} \mathbf{R}_{ij} - \overline{\Sigma} \min \left(\mathbf{R}_{ij}, E_{ij} \right) \right]$$
(4.9)

$$= \overline{\Sigma R_{ii}}$$
(4.10)

i.e. equal to the average annual rainfall itself although, in practice, this value would be slightly reduced due to minor losses to surface runoff and groundwater recharge.

The three lowest values of net rainfall from the 20 stations listed in Table 4.1 are 62 mm (Makhanga), 176 mm (Ngabu) and 197 mm (Mangochi). Since the value for Makhanga is well below the mean value of 113 mm found for S in climatological class No. 1 (see Section 4.4), it is likely that the the original recharge concept is not valid for this station and in most years the soil moisture will remain in deficit throughout the rainy season. Consequently the average annual actual evaporation should be estimated as the same value, 722 mm, as the average annual rainfall (Table 3.2).

4.6 COUNTRYWIDE MEAN VALUE OF SOIL MOISTURE RECHARGE

If the most appropriate value of S is chosen for any particular location in Malaŵi where monthly records of rainfall and potential evaporation exist, annual values of actual evaporation (AE_j') and yield (AY_j') during year j may be found from the formulae:

$$AE_{j}' = \sum_{i=1}^{12} \min (R_{ij}, E_{ij}) + S$$
 (4.11)

$$AY_{j}' = \sum_{i=1}^{12} R_{ij} - \sum_{i=1}^{12} \min (R_{ij}, E_{ij}) - S$$
 (4.12)

As pointed out in Section 4.3, for individual years it is preferable to take the summations shown over the 12 months commencing 1 November.

Bearing in mind the variation of S throughout Malaŵi, described previously, the remainder of this section will examine the estimates of average annual actual evaporation and yield obtained when S is constrained to take the countrywide mean value of 120 mm. Substitution of this value in the appropriate Equations 4.2 and 4.3 yields the values listed in the final two columns of Table 4.1. To compare these values with the corresponding estimates deduced from the catchment waterbalance, Figure 4.4 employs background relationships that are drawn directly from Figure 3.3 which was established when discussing the catchment waterbalance in Section 3.

Figure 4.4 Average annual actual evaporation and yield deduced from the soil moisture recharge method assuming S takes countrywide mean value of 120 mm, compared with background relationships for the same variables deduced from catchment waterbalance

In Fig. 4.4 there is nothing remarkable about the close agreement between the location of the centroid of each set of points and the line of the corresponding background relationship, because the mean value of S was adjusted automatically to 120 mm to provide just this when the individual values of S were being deduced. What is interesting is that, firstly, there are no extreme outliers amongst the calculated values falling far away from the

background relationships. This suggests that the soil moisture recharge concept is a reliable method of estimating actual evaporation and, hence, yield. The second point to note is that the broad rates of increase of average annual actual evaporation and yield against increasing average annual rainfall found for the catchment waterbalance are replicated by the values obtained from the soil moisture recharge method. This latter feature is independent of the value of S chosen, because a change in S in Equation 4.2 and 4.3 will only move all plotted points by the same distance parallel to the ordinate axis, though points representing AAE' will move in the opposite direction to those representing AAY'. Indeed, even if an approximate value, e.g. of 200 mm, were chosen for S based on a rudimentary knowledge of the soils and vegetation in Malaŵi, there would still be a reasonable agreement between the values deduced from each of the two methods.

5. Complementary evaporation

5.1 PREVIEW OF METHODS

The remaining four methods of estimating actual evapotranspiration require only climatological data as input; no soil moisture data or stomatal resistance properties of the vegetation, nor any other additional aridity parameters are needed. One of these methods is that of equilibrium evaporation; the other three are based on the concept of complementary evaporation which is described in the following section.

For ease of comparison all the four methods may be rearranged in a form involving M_e and M_a , the energy and aerodynamic terms of the Penman estimate of short-grass potential evaporation. Neglecting G, the heat flux into the ground, the methods may be written as follows:

Brutsaert-Stricker

$$E_{BS} = 1.52 M_e - M_a$$
 (5.1)

Equilibrium evaporation

 $\mathbf{E}_{\mathbf{F}} = \mathbf{M}_{\mathbf{e}} \tag{5.2}$

Difference

$$E_{\rm D} = M_{\rm e} - M_{\rm a} \tag{5.3}$$

Bouchet

$$E_{BO} = \frac{\gamma}{\Delta} M_e + R_L - M_a$$
 (5.4)

where R_L is the outgoing long-wave radiation, γ the psychrometric constant and Δ the slope of the saturation vapour pressure curve at mean air temperature.

Estimates of actual evapotranspiration obtained from these methods above were compared with AAE, the estimate obtained from the catchment waterbalance described in Section 3. For the convenience of the reader the three most important variables (AAR, E_{PN} and AAE) referred to in this comparison are repeated in Table 5.1

5.2 CONCEPT OF COMPLEMENTARY EVAPORATION

Bouchet (1963) introduced the concept of complementary evaporation, in which a symmetry is assumed between actual and potential evapotranspiration with respect to the evaporative power of the air in the absence of advection. The following description is taken from Brutsaert and Stricker (1979) who provided

| Table 5.1 | Average annual values of rainfall AAR, Penman short |

| Mimosa | 1544 | 1404 | 938 |
| Mzimba | 925 | 1513 | 758 |
| Mzuzu | 1182 | 1316 | 833 |
| Ngabu | 859 | 1840 | 739 |
| Nkhata Bay | 1740 | 1534 | 995 |
| Nkhota Kota | 1759 | 1759 | 1000 |
| Salima | 1426 | 1816 | 904 |
| Thyoto | 1229 | 1427 | 846 |
| Mean | 1130 | 1610 | 819 |

a useful summary of the concept:

Bouchet considered a large uniform surface of regional size, involving characteristic scale lengths of the order of 1 to 10 km, in which the actual evapotranspiration is E. The potential evapotranspiration (E_p) is the evapotranspiration which would take place if the available energy were the only limiting factor; under conditions when E equals E_p , it is denoted by E_{po} . If for one or another reason, independent from the available energy, E decreases below E_{po} , a certain amount of energy becomes available, that is:

$$E_{po} - E = q \tag{5.5}$$

At the scale of the region this decrease of E with respect to E_{po} has only a small impact on the net radiation, and it affects primarily the temperature, the humidity and the turbulence of the air near the ground. As a result, this available energy flux increases E_{p} . Bouchet assumed that if the energy balance remains otherwise unaffected, in the absence of local oasis effects, this increase equals q or:

$$\mathbf{E}_{\mathbf{po}} = \mathbf{E}_{\mathbf{po}} + \mathbf{q} \tag{5.6}$$

The combination of the symmetrical relationships (5.5) and (5.6) yields:

$$E_{p} + E = 2E_{po}$$
 (5.7)

Equation (5.7) is known as the complementary relationship between actual and potential evapotranspiration.

5.3 BRUTSAERT-STRICKER METHOD

Prior to examining the first of the methods it is necessary to define the Priestley-Taylor (1972) estimate of potential evaporation (E_{PT}) as:

$$\mathbf{E}_{\mathbf{PT}} = \boldsymbol{\alpha} \mathbf{M}_{\mathbf{p}} \tag{5.8}$$

where M_e , the energy term of the Penman estimate of short grass potential evaporation, has been previously defined in Equation 2.5 as:

$$M_{e} = \frac{\Delta}{\Delta + \gamma} R_{n}$$
(5.9)

and α is an empirical constant. The value of α was found to be 1.26 by Priestley and Taylor but Brutsaert and Stricker (1979) used this as well as the alternative value of 1.28.

Average annual values of $E_{\rm PT}$ together with the net radiation (R_n) and dimensions less factor $\Delta/(\Delta+\gamma)$ are listed in Table 5.2 for each station. Average monthly values of these three variables are also listed in Appendix 2. As explained in that appendix, because the calculations for Equation 5.9 were undertaken on an individual monthly basis, it is not possible to relate directly the three columns of values listed in Table 5.2.

The version of complementary evaporation proposed by Brutsaert and Stricker (1979) is found by substituting $E_{\rm PT}$ and $E_{\rm PN}$ for $E_{\rm Po}$ and $E_{\rm p}$ in Equation 5.7 and rearranging to give an estimate ($E_{\rm BS}$) of actual evapotranspiration:

$$E_{BS} = 2E_{PT} \cdot E_{PN} \tag{5.10}$$

where E_{PN} is the Penman estimate of short grass potential evaporation defined in Equations 2.1 - 2.3; average annual values are listed in Table 5.1. Substituting in Equation 5.10 these values of E_{PN} , together with those of E_{PT} from Table 5.2, provide the average annual values of E_{BS} listed in Table 5.3.

Equation 5.10 may also be recast in a different format to obtain the expression for estimating E_{BS} mentioned in Section 5.1. Following Equation 2.4, E_{PN} can be expressed in terms of its constituent components:

$$\mathbf{E}_{\mathbf{PN}} = \mathbf{M}_{\mathbf{e}} + \mathbf{M}_{\mathbf{a}} \tag{5.11}$$

Table 5.2 Average annual values of net radiation (water equivalent) R_{pp} dimensionless factor $\Delta/(\Delta+\gamma)$, Priestley-Taylor potential evaporation E_{PT} and incoming short-wave radiation at the surface (water equivalent) R_s

where M_a represents the aerodynamic term defined in Equation 2.6. Assuming α takes the value 1.26, then from Equation 5.8 it follows:

$$E_{\rm PT} = 1.26 \ \rm M_e$$
 (5.12)

Substituting (5.11) and (5.12)_into (5.10) gives

$$E_{\rm RS} = 1.52 \,\,{\rm M_e} - {\rm M_a}$$
 (5.13)

Using in this equation the values of M_e and M_a listed in Table 2.3 provides an alternative way of obtaining the estimates of E_{BS} listed in Table 5.3.

Figure 5.1 illustrates the comparison of actual evapotranspiration estimated by the Brutsaert-Stricker and catchment waterbalance methods. The background waterbalance relationships are copied directly from Fig. 3.3. It was found that

| Climatological | Brutsaert-Stricker | Equilibrium evaporation | Difference | Bouchet |

Table 5.3Average annual values of actual evapotranspiration by
four methods

the majority of E_{BS} values exceeded the average annual rainfall (AAR) observed at the same location; this is possible only if there is a net flow of water into the area which is available to the vegetation for evaporation - a situation which rarely occurs. Even the four E_{BS} values which were less than the average annual rainfall exceeded the catchment waterbalance estimate AAE by at least 39%. At three locations (Mimosa, Mzuzu and Nkhata Bay) the actual evapotranspiration estimate (E_{BS}) exceeded the potential evaporation estimate (E_{PN}). However, on the positive side, the slopes of the two relationships being compared were similar.

It must be concluded that in its present form the Brutsaert-Stricker method does not provide a reliable estimate of actual evapotranspiration for locations in Malaŵi. This is in harmony with the more general conclusion drawn by de Bruin and Stewart (1983) that for inland tropical stations the Brutsaert-Stricker method yields actual evaporation values greater than rainfall for the majority of stations with rainfall less than 1600 mm.

Figure 5.1 Comparison of Brutsaert-Stricker method E_{BS} and catchment waterbalance AAE estimates of actual evapotranspiration

5.4 EQUILIBRIUM EVAPORATION METHOD

In this second method an estimate of actual evapotranspiration (E_E) is given simply by:

$$\mathbf{E}_{\mathbf{F}} = \mathbf{M}_{\mathbf{e}} \tag{5.14}$$

where M_e is the energy term of the Penman estimate of short grass potential evaporation mentioned in Equation 5.9. Although this method is not based on the complementary evaporation concept, it bears certain features in common with the other three methods which make it useful for consideration alongside. This estimate was referred to as the equilibrium evaporation by Slatyer and McIloy (1961) who considered it represents a lower limit to evaporation surfaces.

Brutsaert and Stricker (1979) mention Denmead and McIlroy's (1970) theory that equilibrium evaporation (E_E), could perhaps serve as a simple index for actual evapotranspiration (E) and their tests with hourly data above a wheat crop indicated approximate agreement up to a value of about 25 mW cm⁻², but E was overestimated by E_E at higher rates. Brutsaert and Stricker themselves undertook a comparison between their own method (E_{BS}) and the equilibrium evaporation (E_E) by determining how closely these expressions matched a separate estimate of actual evapotranspiration found from using the energy budget approach for small catchment in The Netherlands during the drought of 1976. They concluded that their method was superior over periods of one to three days but both methods produced similar results with these data over longer periods of the order of a month.

Figure 5.2 illustrates the comparison between the methods of equilibrium evaporation (E_E) and catchment waterbalance (AAE) for Malaŵi. Values of E_E equal to the M_e values shown in Table 2.3 are listed in Table 5.3. Values of E_E for the six lakeshore stations have been omitted from the figure for the sake of clarity; their values are approximately equal to the two highest E_E values shown.

Figure 5.2 Comparison of equilibrium evaporation method E_E and catchment waterbalance AAE estimates of actual evapotranspiration, together with Penman estimates of short grass potential evapotranspiration E_{PN} for upland area stations

It was found that although all E_E values, except Chileka, were less than the corresponding E_{BS} values, they were all more than the AAE values by at least 20%. Over 50% of the E_E values still exceeded the average annual rainfall (AAR). Because M_e is less than $M_e + M_a$ it follows from Equations 5.14 and 5.11 that estimates of actual evapotranspiration (E_E) will always be less than Penman short grass potential evaporation (E_{PN}) as in Fig. 5.2. This figure also shows a further negative feature of the method, namely that E_E does not exhibit any increasing trend with AAR, unlike AAE or even E_{BS} (cf. Fig. 5.1.).

The conclusion drawn is that equilibrium evaporation provides an improved estimate of actual evapotranspiration over the method of Brutsaert-Stricker but sill overestimates in comparison with the corresponding values deduced from the catchment waterbalance.

5.4.1 Choice of E_{po} in the complementary evaporation equation

Some evidence in support of the complementary evaporation concept is provided by the average annual values shown in Fig. 5.2. As actual evapotranspiration (AAE) increases, it will be noted that:

- (a) the potential evapotranspiration (E_{PN}) decreases
- (b) the energy term (M_e) , and hence net radiation (R_n) to which it is closely connected, remains relatively unchanged.

No derivation of the concept from physical principles is offered here. Even if the physical basis of the complementary method is weak, it may prove a unique empirical method for solving many practical problems (de Bruin and Stewart, 1983).

Inspection of Fig. 5.2 reveals some suggestions regarding the choice of variable to represent E_{por} the evaporative power of the air in the absence of advection, in the complementary evaporation equation (5.7). From the form of this equation the value of E_{po} should ideally lie half way between the estimates of AAE and E_{pN} . Comparison of Tables 5.2 and 5.1 reveals that E_{pT} the Priestley-Taylor estimate of potential evaporation, lies much closer to E_{pN} than AAE for Malaŵi locations and for three stations (Mimosa, Mzuzu and Nkhata Bay E_{pT} actually exceeds E_{pN} . This explains why the choice of E_{pT} for E_{p0} in the Brutsaert-Stricker method leads to the overestimates of actual evapotranspiration (E_{BS}) mentioned previously.

The 20 climatological stations were divided into two groups, upland area and rift valley; for each station values of $(E_{PN} + AAE)/2$ were calculated from Table 5.1 and the mean for each group determined as 1163 and 1297 mm. It would be preferable if E_{po} possessed values equal or close to these. A suitable contender is proposed by assuming $E_{po} = E_E$, the equilibrium evaporation which, from Equation 5.14 is simply equal to M_e , the energy term of the Penman estimate of shortgrass potential evaporation. Table 2.4 shows that the mean values of M_e are 1123 and 1267 mm for the upland area and rift valley stations respectively, which differ by only 3.4% and 2.3% from the mean values of $(E_{PN} + AAE)/2$ given above.

5.5 DIFFERENCE METHOD

Substitution of $E_{p0} = M_e$ into the complementary evaporation Equation 5.7 and taking E_{PN} as the potential evapotranspiration gives, after rearrangement, the third estimate of actual evapotranspiration (E_D) where:

$$E_{\rm D} = 2M_{\rm e} - E_{\rm PN} \tag{5.15}$$

By expressing E_{PN} in terms of its two components (Equation 5.11) this expression can be recast in an even simpler form:

$$E_{\rm D} = M_{\rm e} - M_{\rm a} \tag{5.16}$$

Because this estimate of actual evapotranspiration is similar to the expression for the Penman estimate of short grass potential evaporation, but with the sign changed form positive to negative, it will be referred to as the Difference method. Average annual values of E_D are listed in Table 5.3; these may be obtained by substituting either values of $E_{\rm PN}$ from Table 5.1 and $E_{\rm E}$ (=M_e) from Table 5.3 into Equation 5.15 or values of M_e and M_a from Table 2.3 into Equation 5.16.

Figure 5.3 illustrates the comparison between the Difference (E_D) and catchment waterbance (AAE) methods. It was found that all the E_D actual evapotranspiration estimates, except that for Makhanga station, were less than the average annual rainfall (AAR). There was also a slight trend for E_D to increase with increase in AAR. From the inequality:

$$M_e - M_a < M_e < M_e + M_a \tag{5.17}$$

Figure 5.3 Comparison of Difference method E_D and catchment waterbalance AAE estimates of actual evapotranspiration in lakeshore and upland stations

it follows that E_D must be less than all values of not only potential evaporation (E_{PN}) but also equilibrium evaporation (E_E).

Figure 5.4 shows a more direct comparison between the values of E_D from Table 5.3 and AAE from Table 5.1. Fifteen of the 20 values of E_D differ by less than 100 mm from the corresponding value of AAE. It should be recalled here that the standard error of estimate of AAE from Equation 3.4 is, by comparison, 90 mm. The mean of all 20 points using the Difference method underestimates by 73 mm, or 8.9%, the corresponding mean from the catchment waterbalnce method. The five poorly-fitting points are from the stations at Chichiri, Chileka, Chitipa, Nkhota Kota and Salima; a possible explanation for the discrepancies of the last two may lie in the large differences between average annual rainfall for the period 1970-1978 examined and for the longer period 1951-1978 given in van der Velden (1979).

The conclusion drawn in this section is that the Difference method provides a promising technique for estimating actual evapotranspiration at the majority of locations in Malaŵi, but slightly underestimates in comparison with the catchment waterbalance method.

Figure 5.4 Comparison of Difference method E_D and catchment waterbalance AAE estimates of actual evapotranspiration in lakeshore upland stations

5.5.1 Connection between Difference and Brutsaert-Stricker methods

The Brutsaert-Stricker method of estimating actual evapotranspiration is one of the better-known recent versions of the complementary evaporation concept. To understand the relationship between this and the new Difference method, described above it is necessary to refer to Equation 14 of Brutsaert and Stricker's 1979 paper, namely:

$$E = (2 \alpha - 1) \frac{\Delta}{\Delta + \gamma} (R_n - G) - \frac{\gamma}{\Delta + \gamma} E_a$$
 (5.18)

where G represents the ground heat flux, E_a the drying power of the air $[f(U_2)(e_3 - e)]$ as in Equation 2.1, and α the Priestley-Taylor empirical constant as in Equation 5.8. In their application of this expression Brutsaert and Stricker neglected G and adopted values of either 1.26 or 1.28 for α .

In the Difference method G is similarly neglected in Equation 5.18, but instead of the previous values adopted α is taken equal to 1. To convert estimates of actual evapotranspiration which originally used the Brutsaert-Stricker method to those using the Difference method it is necessary to subtract either 0.52 M_e or 0.56 M_e, depending on the value of α adopted, where:

$$M_e = \frac{\Delta}{\Delta + \gamma} R_n \tag{5.19}$$

Consequently the new estimates are alwavs less than those of Brutsaert-Stricker, which may alleviate some of the widespread overestimation noted in Section 5.3. Another expression for determining the Brutsaert-Stricker estimate (E_{BS}) is Equation 5.10 involving the Priestley-Taylor (E_{PT}) and Penman (E_{PN}) potential evaporation estimates:

$$E_{BS} = 2E_{PT} - E_{PN}$$
(5.20)

To convert this to the Difference method it is necessary first to divide the Priestley-Taylor estimate by either 1.26 or 1.28, as the case may be; for example:

$$\frac{2E_{PT}}{1.26} - E_{PN}$$
(5.21)

5.6 BOUCHET METHOD

The last of the complementary evaporation methods entails returning to the expression given in the original paper by Bouchet (1963) which introduced the concept. After establishing the complementary evaporation equation (5.7), Bouchet then derived a second equation, on the basis of additional energy budget considerations, expressing E_{po} in terms of the absorbed short-wave radiation (1 - r) R_s. Substituting this into Equation 5.7 gave:

$$E_{p} + E \in (1 - r) R_{s} = Q$$
 (5.22)

where r is the albedo, R_s the incoming short-wave radiation at the surface and Q is a large-scale (i.e. larger than regional) advection term. In subsequent applications Equation 5.22 has usually been simplified to the following equality:

$$E_{p} + E = (1 - r) R_{s}$$
 (5.23)

The approximate validity of this latter expression has been verified with experimental data for annual periods by Bouchet.

In this present study an estimate (E_{BO}) of actual evapotranspiration (E) was obtained by substituting E_{PN} , the Penman estimate of short grass potential evaporation, for E_p in Equation 5.23 and rearranging:

$$E_{BO} = (1 - r) R_s - E_{PN}$$
 (5.24)

Taking the albedo r = 0.25 and using the average annual values of R_s and $E_{\rm PN}$ listed in Tables 5.2 and 5.1 respectively gives the average annual values of $E_{\rm BO}$ listed in Table 5.3. Average monthly values of R_s are also listed in Appendix 2.

Equation 5.24 may also be recast in a different format to obtain the expression for estimating E_{BO} mentioned in Section 5.1. Equation 2.2 for net radiation (R_n) may be summarized as:

$$R_n = (1 - r) R_s + R_L$$
 (5.25)

where R_L is the outgoing long-wave radiation. Following Equation 5.11 E_{PN} may be expressed in terms of its constituent energy and aerodynamic terms:

$$E_{PN} = M_e + M_a \tag{5.26}$$

Substituting (5.25) and (5.26) into (5.24) gives:

$$E_{BO} = R_n + R_L - M_e - M_a$$
 (5.27)

Making use of the inverse form of Equation 5.9:

$$R_n = \frac{\Delta + \gamma}{\Delta} \quad M_e \tag{5.28}$$

Equation 5.27 reduces to:

$$E_{BO} = \frac{\gamma}{\Delta} M_{e} + R_{L} - M_{a}$$
 (5.29)

For the group of 12 upland area climatological stations the mean average annual values of γ/Δ , M_e and R_L are 0.403, 1123 mm and 580 mm respectively. Bearing in mind that all the original basic calculations were done strictly on a monthly data period, an approximate estimate of the mean value for the sum of the first two terms in Equation 5.29 using the three values given above is 1033 mm; this is only 90 mm lower than the mean value 1123 mm of M_e used in Equation 5.16 as discussed in Section 5.5. This means that for locations in Malaŵi there will be a certain measure of agreement between the Difference (E_D) and Bouchet (E_{BO}) methods. However it must be emphasized that estimates of actual evapotranspiration obtained from any of the methods founded on the complementary evaporation concept are very sensitive to the exact choice of E_{p0} values, since the form of Equation 5.7 dictates that any change in E_{p0} results in a change twice that size in E, if E_p remains unchanged.

Figure 5.5 illustrates the comparison between the Bouchet (E_{BO}) and catchment waterbalance (AAE) methods. It was found that all the E_{BO} actual evapotranspiration values were less than both the average annual rainfall (AAR) and potential evaporation (E_{PN}) . For every station E_{BO} was lower than the corresponding value (E_{D}) obtained from the Difference method; six values were even lower than 500 mm, which would give unreasonably high values for average annual yield at these locations. There was little, if any, trend for E_{BO} to increase with increase in AAR.

In Section 5.5 it was demonstrated that the Difference method slightly underestimated actual evapotranspiration in comparison with the catchment waterbalance method. The conclusion drawn in this present section is that the Bouchet method underestimates actual evapotranspiration by an even greater degree; however it does not suffer from the disadvantages shown by the Brutsaert-Stricker and equilibrium evaporation methods, namely exceeding the average annual rainfall at the majority of stations.

Figure 5.5 Comparison of Bouchet method E_{BO} and catchment waterbalance AAE estimates of actual evapotranspiration

6. Discussion and conclusions

6.1 RAINFALL AND POTENTIAL EVAPORATION

An initial review of rainfall and potential evaporation in Malawi provided the following conclusions. In this region of Central Africa there is, generally, one distinct annual rainy season followed by a long dry season. The spatial variation of average annual rainfall is consistent both in the upland areas and in the rift valley south of Lake Malawi, but is erratic along the western lakeshore. Stations in all areas demonstrate considerable variation from year to year in annual rainfall totals.

In general higher values of Penman short grass potential evaporation (E_{PN}) are estimated along the rift valley floor with lower values on the upland areas. Average annual values of E_{PN} range from 1316 to 1840 mm with a mean of 1610 mm. The Penman open water evaporation (E_0) is approximately 25% larger than E_{PN} and exhibits similar spatial variation. Both E_{PN} and E_0 demonstrate little variation from year to year at all stations.

The term E_{PN} may be usefully expressed as the sum of its components, the energy term (M_e) and the aerodynamic term (M_a) . As one factor influencing higher values of E_{PN} , it is particularly noticeable that all the higher values of M_e occur at rift valley stations; the mean value of M_e for upland area stations is 11% less than the corresponding value for the rift valley. Annual values of M_e show very little variation from year to year.

Values of M_a are considerably smaller than M_e , but show both greater spatial variation and greater year-to-year variation than M_e . The mean value of M_a for upland area stations is 16% less than the corresponding value for the rift valley but, unlike the value for M_e , not all individual rift valley station values are greater than the individual upland area values. Values of M_a appear to be depressed in the tea cultivation areas but enhanced on the leeward side of high ground.

To highlight these variations a plot of M_a against M_e allowed the 20 climatological stations to be divided into five classes to distinguish their climatic properties.

6.2 ACTUAL EVAPOTRANSPIRATION

The six methods (listed in Table 6.1) used in this study to estimate actual evapotranspiration were applied to data from 20 climatological stations, eight of which were located down in the rift valley and 12 on upland areas. Catchment waterbalance (AAE) was considered the most reliable method, with which the other five were compared.

Three of the methods did not prove reliable for locations in Malawi: Brutsaert-Stricker (E_{BS}), equilibrium evaporation (E_E) and Bouchet (E_{BO}).

| Method | Formula | Actual evapotranspiration Mean (mm) |
|-------------------------|--|---|
| Catchment waterbalance | AAE = 0.29 AAR + 490 | 819 |
| Soil moisture recharge | AAE' = $\overline{\Sigma_{min} (R_{ij}, E_{ij})}$ + S | 818 |
| Brutsaert-Stricker | Е _{BS} = 1.52 М _е – М _а | 1360 |
| Equilibrium evaporation | E _E - M _e | 1180 |
| Difference | $E_D = M_e - M_a$ | 746 |
| Bouchet | $E_{BO} = \frac{\gamma}{\Delta} M_e + R_L - M_e$ | A _a 584 |

Table 6.1 The countrywide mean value of average annual actual evapotranspiration estimated by the six different methods

The main drawbacks were that firstly the majority of E_{BS} and E_E values exceeded the rainfall (AAR), secondly E_E and E_{BO} did not increase with increasing rainfall, and thirdly, as demonstrated in Table 6.1, E_{BS} substantially overestimated AAE, whilst E_E and E_{BO} , though closer to AAE, over- and underestimated respectively.

The remaining three methods are all considered suitable for practical use in Malaŵi; Catchment waterbalance (AAE), Soil moisture recharge (AAE') and Difference (E_D). Greatest reliance can be placed on the catchment waterbalance method for two reasons: first, it is based on data drawn from a large number of catchments (38) spread throughout the country; and second, it is valid for the widest range of rainfall, 700 to 2100 mm. The formula in Table 6.1 shows that actual evapotranspiration (AAE) increases slightly with increasing rainfall (AAR). If AAE is expressed as a fraction of E_{PN} (the Penman estimate of short grass potential evaporation) it is found to vary from 39 to 67% with a mean of 51%.

The concept underlying the soil moisture recharge method is particularly appropriate for climates, such as that in Malaŵi, which have a single rainy season. When fitted to the data, the formula in Table 6.1 exhibits several encouraging features: all values of AAE' are less than or equal to the rainfall; there are no extreme outliers; the trend of increasing actual evapotranspiration with increasing rainfall is replicated. The main disadvantage concerns the estimation of soil moisture recharge (S). By comparing this method with that of the catchment waterbalance, S was found empirically to vary between 34 and 209 mm for individual stations, with a countrywide mean of 120 mm. It would be preferable if S could be determined from an independent field soil survey. The close agreement between the mean values of AAE' and AAE in Table 6.1 is not significant because, in the absence of such a field survey, the empirically derived mean value 120 mm was assumed for S. However it does indicate that if an approximate value, say of 200 mm, was chosen for S based on a rudimentary knowledge of soils and vegetation in Malaŵi, there would still be a reasonable agreement between the values deduced from each of the two methods AAE' and AAE.

The well-known formula for estimating Penman short grass potential evaporation is:

$$E_{PN} = \frac{\Delta}{\Delta + \gamma} R_n + \frac{\gamma}{\Delta + \gamma} f(U_2) (e_3 - e)$$
(6.1)

where the albedo r is set equal to 0.25 in the net radiation term R_n . In the difference method an hypothesis for estimating actual evapotranspiration (E_D) is proposed which employs the same two major terms as in the formula for E_{PN} above but, instead of their sum, it takes their difference:

$$E_{D} = \frac{\Delta}{\Delta + \gamma} R_{n} - \frac{\gamma}{\Delta + \gamma} f(U_{2}) (e_{s} - e)$$
(6.2)

When fitted to the data, E_D gives values which show a slight trend to increase with increasing rainfall, and for which all but one are less than the rainfall. From Table 6.1 it is seen that the countrywide mean value of E_D slightly underestimates the corresponding value of AAE by 9%. However the individual station values of the Difference method demonstrate greater scatter than those of the soil moisture recharge method AAE'.

Before concluding it should, however, be recalled that these methods for estimating actual evapotranspiration are applicable only under the following restraints (see also Section 1.4):

- a) the evaporating surface is mixed vegetation
- b) the estimate is of annual, rather than monthly, values of actual evapotranspiration and
- c) the estimate is primarily a regional rather than a site-specific value of actual evapotranspiration.

Although some of the methods can be adapted to estimate monthly values, further research is required to see whether this can be justified.

6.3 COMPLEMENTARY EVAPORATION

The difference method (E_D) and the methods of Brutsaert-Stricker (E_{BS}) and Bouchet (E_{BO}) are founded on the concept of complementary evaporation (Bouchet, 1963):

 $\mathbf{E}_{\mathbf{p}} + \mathbf{E} = 2\mathbf{E}_{\mathbf{p}\mathbf{O}} \tag{6.3}$

in which a symmetry is assumed between actual E and potential evapotranspiration (E_p) with respect to the evaporative power of the air in the absence of advection (E_{po}) .

Some evidence in support of the concept, at least for annual periods, is provided by analysis of the Malaŵi data: as the actual evapotranspiration (AAE) increases, firstly the potential evapotranspiration (E_{PN}) decreases and secondly the net radiation (R_n) remains relatively unchanged; however this evidence is not firm enough to be conclusive.

Regarding the choice of a suitable variable to represent E_{po} , ideally it needs to lie halfway between E_{PN} and AAE to maintain the symmetry inherent in Equation 6.3. In the Brutsaert-Stricker method the Priestley-Taylor estimate of potential evaporation (E_{PT}) is chosen for E_{po} . For stations in Malaŵi it is found that E_{PT} lies much closer to E_{PN} than AAE; this leads to the substantial overestimates by E_{BS} values and makes the method unsuitable for use in this country. In contrast, in the Difference method the equilibrium evaporation (E_E) is chosen to represent E_{po} . The reason for this choice is that mean values of $E_{\rm E}$ for the two groups of upland area and rift valley stations were only 3% less than the corresponding ideal values of (E_{PN} + AAE)/2. This method gives estimates (E_D) of actual evapotranspiration that are always less than E_{BS} values. From the form of the formula (Table 6.1) it can also be demonstrated that E_{D} is always less than both the equilibrium evaporation (E_E) and the potential evapotranspiration (E_{PN}). Therefore it may be concluded that the choice of E_E for E_{po} leads to a method more suitable for use in Malaŵi. However it must be emphasized that estimates of actual evapotranspiration obtained from any of the methods founded on the complementary evaporation concept are very sensitive to the exact choice of variable for E_{po} , since the form of Equation 6.3 dictates that any change in E_{po} , results in a change twice that size in E, if E_p remains unchanged.

No derivation of the new Difference method from physical principles is offered in this report. Even if the physical basis is weak it may prove a useful empirical method for solving practical problems. Further work on the theoretical aspects together with practical testing under different climates in other countries are required to establish whether this hypothesis has any validity other than as an empirical method for estimating actual evapotranspiration in Malawi.

Acknowledgements

This study formed part of the project entitled 'Estimation of Actual Evaporation from Climatological Data' undertaken at the Institute of Hydrology and funded by the UK Overseas Development Administration.

The climatological observations were provided by the Malaŵi Meteorological Service, P.O. Box 2, Chileka, Malaŵi, Central Africa. The base map was provided by the Department of Surveys, Blantyre, Malaŵi.

The authors are very grateful to: Henk de Bruin, whilst on leave from the Royal Netherlands Meteorological Institute, for considerable assistance with computer programs; H.E. Dandaula of the Malaŵi Meteorological Service for providing the climatological data and comments on the climate in Malaŵi; colleagues at IH for comments and discussion during the early part of the study; and finally Richard Stinton and Andrew Hindson for assistance with the computations and preparation of the data appendix.

Appendix 1 Practical calculation of potential evaporation

This appendix contains in greater detail the practical background to the calculation of potential evaporation for Malaŵi.

CORRECTIONS UNDERTAKEN TO THE OBSERVATIONS BEFORE PROCESSING

- New climatological stations were opened at Ngabu on 17 October 1971 and at Dwangwa on 3 December 1971.
- The previous name of the station at Thyolo was Cholo. The previous name of the station at Mangochi was Mangoche, and prior to that Fort Johnson.
- The instruments at Mangochi station were moved on 2 September 1971 to a new site 500 yards to the south-east.
- At Lilongwe the observations from the 6 ft. high anemometer were missing for all months of the 1970-1978 record. Readings were taken instead form the Munro cup anemograph, which was assumed to be mounted at the standard height of 10 m. A factor of 0.78, as recommended in the British Meteorological Office observer's handbook, was applied to all windspeeds to reduce them to the equivalent speeds found at 2 m height.
- Observations of windspeed, dew point temperature, mean air temperature, sunshine hours and rainfall were missing for occasional months for all stations, as listed in Table A1.1. The average of the observations for the same month in all the remaining years was used to fill in these missing values for each variable.

CALCULATION OF MINOR VARIABLES

The explanation and source of the variables used in the calculation of potential evaporation, described in Equations 2.1-2.3, are given in Table A1.2.

ANOMALIES IN THE PROCESSED DATA

Inspection of the computer listings of processed potential evaporation data revealed a number of anomalies which are listed in Table A1.3. The remaining seven stations, Bvumbwe, Chitedze, Chitipa, Karonga, Mzimba, Nkhota Kota and Thyolo did not reveal any easily recognisable anomalies.

Table: A1.1 Months in which observations of certain variables were missing at the climatological stations

| Variable | Source |
|----------------|--|
| R | Rainfall measured in a Snowdon pattern raingauge with rim at 2ft 6ins above ground level |
| U2 | Windspeed measured in a 6ft high cup anemometer, which was assumed equal to the speed at 2m height |
| Т _а | Mean air temperature taken as the mean of observations from the maximum and minimum thermometers |
| | Stefan-Boltzman constant: 5.67 x 10 ⁻⁸ W m ⁻² K ⁻⁴ |
| n N N | n is hours of bright sunshine observed on a Campbell-Stokes recorder, with WMO type reductions; N is maximum possible hours of bright sunshine calculated from values of latitude and day of year. |
| R _a | Incoming short-wave radiation at the top of the earth's atmosphere calculated from values of latitude, day of year and solar constant |
| | Saturation vapour pressure at mean air temperature; e _s is a function of temperature T _a |
| | Vapour pressure is a function of the mean dewpoint temperature, which is taken as the mean of the dewpoint temperatures of 0800 and 1400 hours |
| | Slope of saturation vapour pressure curve at mean air temperature. Δ is a function of temperature T_a |
| | Psychrometric constant is taken as a function of altitude and temperature T _a |

Table: A1.2Source of variables used in calculation of potential
evaporation

| Climatological Station | Anomalics |
|---------------------------|---|
| Chichiri | Windspeed decreasing over period 1972-1974 |
| | Mean air temperature error in August 1973 |
| Chileka | Vapour pressure error February 1971 |
| Dedza | March rainfall much higher in 1974-1978 than in 1970-1973 |
| | Low potential evaporation estimates in 1974 and 1978 |
| Dwangwa | Rainfall in May 1974, but not in May 1973, affects radiation term |
| Lilongwe | Vapour pressure errors in August 1970 and July 1971 March rainfall much higher in 1974-1978 than in 1970-1973 Low potential evaporation estimates in 1974 and 1978 |
| Makhanga | Rainfall does not have same pattern as Ngabu |
| Makoka | Rainfall error in January 1976 |
| | Doubtful rainfall value in January 1970, since it differs greatly |
| | from values at Chileka and Chichiri |
| Mangochi | In general processed variables, except rainfall, very similar to same variables recorded at Salima; however 1970-1978 rainfall recorded at Salima is not representative of long-term average there |
| | In general processed variables very similar to same variables recorded at Ngabu Very high rainfall recorded in 1978, as it was also for other |
| | stations on the lakeshore |
| Mimosa | Mean air temperature error in February 1978 Vapour pressure error in May 1970 Rainfall agrees quite closely with that recorded at Thyolo station |
| Mzuzu | Mean air temperature error in November 1974 Windspeed error in August 1977 Some doubtful values in vapour pressure deficits Good correlation between values of M _e and n/N |
| Ngabu | Extremely high value of M _a recorded in October 1977 |
| Nkhata Bay | Windspeed gradually decreasing over 1970-1978 Thom-Oliver wind function RA gradually increasing over 1970-1978 |
| Salima | Rainfall recorded during 1970-1978 is not representative of long-term average |

Table: A1.3 Anomalies discovered in the processed potentialevaporation data

Appendix 2 Average monthly values of rainfall and selected evaporation variables

This appendix lists the average monthly values of the most useful nine variables at each of the 20 climatological stations. For each variable separate tables give the mean and coefficient of variation over the period of record, which is nine years for all but two of the stations. All values of the mean expressed in units of mm were rounded to the nearest mm; consequently some average annual values may not exactly equal the sum of the average monthly values shown. The coefficient of variation is a measure of the year-to-year change in a variable; a star in a column indicates that its values is indeterminate, for example if, for a certain month, all annual values of rainfall are zero.

The 18 tables in this appendix are arranged as shown below:

| Variable | Mean | Coefficient of variation |
|-----------------|-----------|--------------------------|
| | Table No. | Table No. |
| R | A2.1A | A2.1B |
| E _{PN} | A2.2A | A2.2B |
| E | A2.3A | A2.3B |
| M | A2.4A | A2.4B |
| Ma | A2.5A | A2.5B |
| E _{PT} | A2.6A | A2.6B |
| R_ | A2.7A | A2.7B |
| ΔΪ (Δ+γ) | A2.8A | A2.8B |
| R. | A2.9A | A2.9B |

From these listings of nine variables it is possible to calculate average monthly values for any of the other major variables mentioned in the main text, for example:

Brutsaert and Stricker actual evaporation estimates

$$E_{BS} = 2E_{PT} - E_{PN}$$
(A2.1)

| or | E _{BS} | = | 1.52M _e - | M _a | (4 | A2.2) | |
|----|-----------------|---|----------------------|----------------|----|-------|--|
|----|-----------------|---|----------------------|----------------|----|-------|--|

Actual evaporation estimated from the Difference method

$$E_{D} = 2M_{e} - E_{PN} \tag{A2.3}$$

or
$$E_D = M_e - M_a$$
 (A2.4)
$$E_{\rm D} = \frac{2E_{\rm PT}}{1.26} \cdot E_{\rm PN} \tag{A2.5}$$

Outgoing long-wave radiation

 $R_{L} = (1 - r) R_{s} - R_{n}$ (A2.6)

with r = 0.25

Bouchet actual evaporation estimate

 $E_{BO} = (1 - r) R_s - E_{PN}$ (A2.7)

with r = 0.25
or E_{BO} =
$$\frac{\gamma}{\Lambda}$$
 M_e + R_L - M_a (A2.8)

Dimensionless factors

$$\frac{\gamma}{\Delta + \gamma} = \frac{\Delta}{\Delta + \gamma}$$
(A2.9)

$$\frac{\gamma}{\Delta} \qquad \left[\frac{\Delta}{\Delta+\gamma}\right]^{-1} \tag{A2.10}$$

It should be noted that expression:

$$M_e = \frac{\Delta}{\Delta + \gamma} R_n \tag{A2.11}$$

was evaluated using the individual monthly values of $\Delta/(\Delta+\gamma)$ and R_n for each station. Since this is a product of two variables it follows that:

$$\overline{M}_{e} \neq \overline{\frac{\Delta}{\Delta + \gamma}} \overline{R}_{n}$$
(A2.12)

where the bars denote average monthly values or average annual values. Therefore the values of M_e , $\Delta/(\Delta+\gamma)$ and R_n in Tables A2.4A, A2.8A and A2.7A cannot be directly related; in practice, although the inequality (A2.12) is true for average annual values, the two sides of the expression show close agreement for average monthly values.

Table A2.1 Average monthly values of rainfall R for 1970-1978

a) Mean (mm)

Figure A3.2 Coefficient of variation (%) of annual values of rainfall R

Figure A.3.3 Average annual values of Penman short grass potential evaporation E_{PN} (mm)

Figure A3.4 Average annual values of Penman open water evaporation E_o (mm)

Figure A3.6 Average annual values (mm) of the aerodynamic term M_a of Penman short grass potential evaporation

Appendix 4 Soil moisture recharge method

This appendix illustrates the practical application of the soil moisture recharge method to calculate actual evaporation and yield from nine years of records at Chitedze climatological station.

Tables A4.1 and A4.2 display the monthly values of rainfall (R_{ij}) and potential evaporation (E_{ij}). An earlier version of Penman short grass potential evaporation (E_{PN}) is substituted for E_{ij} in this calculation, but it differs from the final version displayed in Table A2.2A in Appendix 2 by less than 1%.

The least value of either R_{ij} or E_{ij} for each month is displayed as min (R_{ij}, E_{ij}) in Table A4.3. This latter value is subtracted from the R_{ij} values to give the values of R_{ij} - min (R_{ij}, E_{ij}) displayed in Table A1.4.

Over each year the monthly values are totalled to give the values displayed in the right hand column of each table. The mean of these latter values is calculated over nine years and tabulated on the bottom line.

From Equation 4.2 in Section 4 of the report and Table A4.3, the average annual actual evaporation AAE' is found from :

$$AAE' = 623 + S$$
 (A4.1)

where S is the estimate of soil moisture recharge. From Equation 4.3 and Table A4.4 the average annual yield (AAY') is found from:

AAY' = 360 - S

If S is assumed to take the value 120 mm, that is the countrywide mean found for Mala^V is by comparison with the catchment waterbalance, then it follows that AAE' = 743 mm and AAY' = 240 mm.
